# ====================================================================
# Written by Andy Polyakov <appro@fy.chalmers.se> for the OpenSSL
# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================
#
# Version 4.3.
#
# You might fail to appreciate this module performance from the first
# try. If compared to "vanilla" linux-ia32-icc target, i.e. considered
# to be *the* best Intel C compiler without -KPIC, performance appears
# to be virtually identical... But try to re-configure with shared
# library support... Aha! Intel compiler "suddenly" lags behind by 30%
# [on P4, more on others]:-) And if compared to position-independent
# code generated by GNU C, this code performs *more* than *twice* as
# fast! Yes, all this buzz about PIC means that unlike other hand-
# coded implementations, this one was explicitly designed to be safe
# to use even in shared library context... This also means that this
# code isn't necessarily absolutely fastest "ever," because in order
# to achieve position independence an extra register has to be
# off-loaded to stack, which affects the benchmark result.
#
# Special note about instruction choice. Do you recall RC4_INT code
# performing poorly on P4? It might be the time to figure out why.
# RC4_INT code implies effective address calculations in base+offset*4
# form. Trouble is that it seems that offset scaling turned to be
# critical path... At least eliminating scaling resulted in 2.8x RC4
# performance improvement [as you might recall]. As AES code is hungry
# for scaling too, I [try to] avoid the latter by favoring off-by-2
# shifts and masking the result with 0xFF<<2 instead of "boring" 0xFF.
#
# As was shown by Dean Gaudet <dean@arctic.org>, the above note turned
# void. Performance improvement with off-by-2 shifts was observed on
# intermediate implementation, which was spilling yet another register
# to stack... Final offset*4 code below runs just a tad faster on P4,
# but exhibits up to 10% improvement on other cores.
#
# Second version is "monolithic" replacement for aes_core.c, which in
# addition to AES_[de|en]crypt implements private_AES_set_[de|en]cryption_key.
# This made it possible to implement little-endian variant of the
# algorithm without modifying the base C code. Motivating factor for
# the undertaken effort was that it appeared that in tight IA-32
# register window little-endian flavor could achieve slightly higher
# Instruction Level Parallelism, and it indeed resulted in up to 15%
# better performance on most recent µ-archs...
#
# Third version adds AES_cbc_encrypt implementation, which resulted in
# up to 40% performance imrovement of CBC benchmark results. 40% was
# observed on P4 core, where "overall" imrovement coefficient, i.e. if
# compared to PIC generated by GCC and in CBC mode, was observed to be
# as large as 4x:-) CBC performance is virtually identical to ECB now
# and on some platforms even better, e.g. 17.6 "small" cycles/byte on
# Opteron, because certain function prologues and epilogues are
# effectively taken out of the loop...
#
# Version 3.2 implements compressed tables and prefetch of these tables
# in CBC[!] mode. Former means that 3/4 of table references are now
# misaligned, which unfortunately has negative impact on elder IA-32
```

```
# implementations, Pentium suffered 30% penalty, PIII - 10%.
#
# Version 3.3 avoids L1 cache aliasing between stack frame and
# S-boxes, and 3.4 - L1 cache aliasing even between key schedule. The
# latter is achieved by copying the key schedule to controlled place in
# stack. This unfortunately has rather strong impact on small block CBC
# performance, ~2x deterioration on 16-byte block if compared to 3.3.
#
# Version 3.5 checks if there is L1 cache aliasing between user-supplied
# key schedule and S-boxes and abstains from copying the former if
# there is no. This allows end-user to consciously retain small block
# performance by aligning key schedule in specific manner.
#
# Version 3.6 compresses Td4 to 256 bytes and prefetches it in ECB.
#
# Current ECB performance numbers for 128-bit key in CPU cycles per
# processed byte [measure commonly used by AES benchmarkers] are:
#
#               small footprint         fully unrolled
# P4            24                      22
# AMD K8        20                      19
# PIII          25                      23
# Pentium       81                      78
#
# Version 3.7 reimplements outer rounds as "compact." Meaning that
# first and last rounds reference compact 256 bytes S-box. This means
# that first round consumes a lot more CPU cycles and that encrypt
# and decrypt performance becomes asymmetric. Encrypt performance
# drops by 10-12%, while decrypt - by 20-25%:-( 256 bytes S-box is
# aggressively pre-fetched.
#
# Version 4.0 effectively rolls back to 3.6 and instead implements
# additional set of functions, _[x86|sse]_AES_[en|de]crypt_compact,
# which use exclusively 256 byte S-box. These functions are to be
# called in modes not concealing plain text, such as ECB, or when
# we're asked to process smaller amount of data [or unconditionally
# on hyper-threading CPU]. Currently it's called unconditionally from
# AES_[en|de]crypt, which affects all modes, but CBC. CBC routine
# still needs to be modified to switch between slower and faster
# mode when appropriate... But in either case benchmark landscape
# changes dramatically and below numbers are CPU cycles per processed
# byte for 128-bit key.
#
#               ECB encrypt     ECB decrypt     CBC large chunk
# P4            56[60]          84[100]         23
# AMD K8        48[44]          70[79]          18
# PIII          41[50]          61[91]          24
# Core 2        32[38]          45[70]          18.5
# Pentium       120             160             77
#
# Version 4.1 switches to compact S-box even in key schedule setup.
#
# Version 4.2 prefetches compact S-box in every SSE round or in other
# words every cache-line is *guaranteed* to be accessed within ~50
# cycles window. Why just SSE? Because it's needed on hyper-threading
# CPU! Which is also why it's prefetched with 64 byte stride. Best
# part is that it has no negative effect on performance:-)
#
# Version 4.3 implements switch between compact and non-compact block
# functions in AES_cbc_encrypt depending on how much data was asked
# to be processed in one stroke.
#
##############################################################################
# Timing attacks are classified in two classes: synchronous when
# attacker consciously initiates cryptographic operation and collects
# timing data of various character afterwards, and asynchronous when
```

```
# malicious code is executed on same CPU simultaneously with AES,
# instruments itself and performs statistical analysis of this data.
#
# As far as synchronous attacks go the root to the AES timing
# vulnerability is twofold. Firstly, of 256 S-box elements at most 160
# are referred to in single 128-bit block operation. Well, in C
# implementation with 4 distinct tables it's actually as little as 40
# references per 256 elements table, but anyway... Secondly, even
# though S-box elements are clustered into smaller amount of cache-
# lines, smaller than 160 and even 40, it turned out that for certain
# plain-text pattern[s] or simply put chosen plain-text and given key
# few cache-lines remain unaccessed during block operation. Now, if
# attacker can figure out this access pattern, he can deduct the key
# [or at least part of it]. The natural way to mitigate this kind of
# attacks is to minimize the amount of cache-lines in S-box and/or
# prefetch them to ensure that every one is accessed for more uniform
# timing. But note that *if* plain-text was concealed in such way that
# input to block function is distributed *uniformly*, then attack
# wouldn't apply. Now note that some encryption modes, most notably
# CBC, do mask the plain-text in this exact way [secure cipher output
# is distributed uniformly]. Yes, one still might find input that
# would reveal the information about given key, but if amount of
# candidate inputs to be tried is larger than amount of possible key
# combinations then attack becomes infeasible. This is why revised
# AES_cbc_encrypt "dares" to switch to larger S-box when larger chunk
# of data is to be processed in one stroke. The current size limit of
# 512 bytes is chosen to provide same [diminishigly low] probability
# for cache-line to remain untouched in large chunk operation with
# large S-box as for single block operation with compact S-box and
# surely needs more careful consideration...
#
# As for asynchronous attacks. There are two flavours: attacker code
# being interleaved with AES on hyper-threading CPU at *instruction*
# level, and two processes time sharing single core. As for latter.
# Two vectors. 1. Given that attacker process has higher priority,
# yield execution to process performing AES just before timer fires
# off the scheduler, immediately regain control of CPU and analyze the
# cache state. For this attack to be efficient attacker would have to
# effectively slow down the operation by several *orders* of magnitute,
# by ratio of time slice to duration of handful of AES rounds, which
# unlikely to remain unnoticed. Not to mention that this also means
# that he would spend correspondigly more time to collect enough
# statistical data to mount the attack. It's probably appropriate to
# say that if adeversary reckons that this attack is beneficial and
# risks to be noticed, you probably have larger problems having him
# mere opportunity. In other words suggested code design expects you
# to preclude/mitigate this attack by overall system security design.
# 2. Attacker manages to make his code interrupt driven. In order for
# this kind of attack to be feasible, interrupt rate has to be high
# enough, again comparable to duration of handful of AES rounds. But
# is there interrupt source of such rate? Hardly, not even 1Gbps NIC
# generates interrupts at such raging rate...
#
# And now back to the former, hyper-threading CPU or more specifically
# Intel P4. Recall that asynchronous attack implies that malicious
# code instruments itself. And naturally instrumentation granularity
# has be noticeably lower than duration of codepath accessing S-box.
# Given that all cache-lines are accessed during that time that is.
# Current implementation accesses *all* cache-lines within ~50 cycles
# window, which is actually *less* than RDTSC latency on Intel P4!

594 ########################################################################
595 # Why not xmm registers? Short answer. It was actually tested and
596 # was not any faster, but *contrary*, most notably on Intel CPUs.
597 # Longer answer. Main advantage of using mm registers is that movd
598 # latency is lower, especially on Intel P4. While arithmetic
599 # instructions are twice as many, they can be scheduled every cycle
600 # and not every second one when they are operating on xmm register,
601 # so that "arithmetic throughput" remains virtually the same. And
602 # finally the code can be executed even on elder SSE-only CPUs:-)

# Written by Andy Polyakov <appro@fy.chalmers.se> for the OpenSSL
# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================
#
# Version 2.1.
#
# aes-*-cbc benchmarks are improved by >70% [compared to gcc 3.3.2 on
# Opteron 240 CPU] plus all the bells-n-whistles from 32-bit version
# [you'll notice a lot of resemblance], such as compressed S-boxes
# in little-endian byte order, prefetch of these tables in CBC mode,
# as well as avoiding L1 cache aliasing between stack frame and key
# schedule and already mentioned tables, compressed Td4...
#
# Performance in number of cycles per processed byte for 128-bit key:
#
#               ECB encrypt     ECB decrypt     CBC large chunk
# AMD64         33              41              13.0
# EM64T         38              59              18.6(*)
# Core 2        30              43              14.5(*)
#
# (*) with hyper-threading off

#
# June 2011
#
# This is AESNI-CBC+SHA1 "stitch" implementation. The idea, as spelled
# in http://download.intel.com/design/intarch/papers/323686.pdf, is
# that since AESNI-CBC encrypt exhibit *very* low instruction-level
# parallelism, interleaving it with another algorithm would allow to
# utilize processor resources better and achieve better performance.
# SHA1 instruction sequences(*) are taken from sha1-x86_64.pl and
# AESNI code is weaved into it. Below are performance numbers in
# cycles per processed byte, less is better, for standalone AESNI-CBC
# encrypt, sum of the latter and standalone SHA1, and "stitched"
# subroutine:
#
#               AES-128-CBC     +SHA1           stitch      gain
# Westmere      3.77[+5.6]      9.37            6.65        +41%
# Sandy Bridge  5.05[+5.2(6.3)] 10.25(11.35)    6.16(7.08)  +67%(+60%)
#
#               AES-192-CBC
# Westmere      4.51            10.11           6.97        +45%
# Sandy Bridge  6.05            11.25(12.35)    6.34(7.27)  +77%(+70%)
#
#               AES-256-CBC
# Westmere      5.25            10.85           7.25        +50%
# Sandy Bridge  7.05            12.25(13.35)    7.06(7.70)  +74%(+73%)
#
# (*)   There are two code paths: SSSE3 and AVX. See sha1-568.pl for
#       background information. Above numbers in parentheses are SSSE3
#       results collected on AVX-capable CPU, i.e. apply on OSes that
#       don't support AVX.
#
# Needless to mention that it makes no sense to implement "stitched"
# *decrypt* subroutine. Because *both* AESNI-CBC decrypt and SHA1
# fully utilize parallelism, so stitching would not give any gain
# anyway. Well, there might be some, e.g. because of better cache
# locality... For reference, here are performance results for
# standalone AESNI-CBC decrypt:
#
#               AES-128-CBC     AES-192-CBC     AES-256-CBC
# Westmere      1.31            1.55            1.80
# Sandy Bridge  0.93            1.06            1.22

# ====================================================================
# Written by Andy Polyakov <appro@fy.chalmers.se> for the OpenSSL
# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================
#
# This module implements support for Intel AES-NI extension. In
# OpenSSL context it’s used with Intel engine, but can also be used as
# drop-in replacement for crypto/aes/asm/aes-586.pl [see below for
# details].
#
# Performance.
#
# To start with see corresponding paragraph in aesni-x86_64.pl...
# Instead of filling table similar to one found there I’ve chosen to
# summarize *comparison* results for raw ECB, CTR and CBC benchmarks.
# The simplified table below represents 32-bit performance relative
# to 64-bit one in every given point. Ratios vary for different
# encryption modes, therefore interval values.
#
#       16-byte     64-byte     256-byte    1-KB        8-KB
#       53-67%      67-84%      91-94%      95-98%      97-99.5%
#
# Lower ratios for smaller block sizes are perfectly understandable,
# because function call overhead is higher in 32-bit mode. Largest
# 8-KB block performance is virtually same: 32-bit code is less than
# 1% slower for ECB, CBC and CCM, and ~3% slower otherwise.

# January 2011
#
# See aesni-x86_64.pl for details. Unlike x86_64 version this module
# interleaves at most 6 aes[enc|dec] instructions, because there are
# not enough registers for 8x interleave [which should be optimal for
# Sandy Bridge]. Actually, performance results for 6x interleave
# factor presented in aesni-x86_64.pl (except for CTR) are for this
# module.

# April 2011
#
# Add aesni_xts_[en|de]crypt. Westmere spends 1.50 cycles processing
# one byte out of 8KB with 128-bit key, Sandy Bridge - 1.09.

# _aesni_[en|de]cryptN are private interfaces, N denotes interleave
# factor. Why 3x subroutine were originally used in loops? Even though
# aes[enc|dec] latency was originally 6, it could be scheduled only
# every *2nd* cycle. Thus 3x interleave was the one providing optimal
# utilization, i.e. when subroutine's throughput is virtually same as
# of non-interleaved subroutine [for number of input blocks up to 3].
# This is why it makes no sense to implement 2x subroutine.
# aes[enc|dec] latency in next processor generation is 8, but the
# instructions can be scheduled every cycle. Optimal interleave for
# new processor is therefore 8x, but it's unfeasible to accommodate it
# in XMM registers addreassable in 32-bit mode and therefore 6x is
# used instead...

#
# ====================================================================
# Written by Andy Polyakov <appro@fy.chalmers.se> for the OpenSSL
# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================
#
# This module implements support for Intel AES-NI extension. In
# OpenSSL context it's used with Intel engine, but can also be used as
# drop-in replacement for crypto/aes/asm/aes-x86_64.pl [see below for
# details].
#
# Performance.
#
# Given aes(enc|dec) instructions' latency asymptotic performance for
# non-parallelizable modes such as CBC encrypt is 3.75 cycles per byte
# processed with 128-bit key. And given their throughput asymptotic
# performance for parallelizable modes is 1.25 cycles per byte. Being
# asymptotic limit it's not something you commonly achieve in reality,
# but how close does one get? Below are results collected for
# different modes and block sized. Pairs of numbers are for en-/
# decryption.
#
#       16-byte     64-byte     256-byte    1-KB        8-KB
# ECB   4.25/4.25   1.38/1.38   1.28/1.28   1.26/1.26   1.26/1.26
# CTR   5.42/5.42   1.92/1.92   1.44/1.44   1.28/1.28   1.26/1.26
# CBC   4.38/4.43   4.15/1.43   4.07/1.32   4.07/1.29   4.06/1.28
# CCM   5.66/9.42   4.42/5.41   4.16/4.40   4.09/4.15   4.06/4.07
# OFB   5.42/5.42   4.64/4.64   4.44/4.44   4.39/4.39   4.38/4.38
# CFB   5.73/5.85   5.56/5.62   5.48/5.56   5.47/5.55   5.47/5.55
#
# ECB, CTR, CBC and CCM results are free from EVP overhead. This means
# that otherwise used 'openssl speed -evp aes-128-??? -engine aesni
# [-decrypt]' will exhibit 10-15% worse results for smaller blocks.
# The results were collected with specially crafted speed.c benchmark
# in order to compare them with results reported in "Intel Advanced
# Encryption Standard (AES) New Instruction Set" White Paper Revision
# 3.0 dated May 2010. All above results are consistently better. This
# module also provides better performance for block sizes smaller than
# 128 bytes in points *not* represented in the above table.
#
# Looking at the results for 8-KB buffer.
#
# CFB and OFB results are far from the limit, because implementation
# uses "generic" CRYPTO_[c|o]fb128_encrypt interfaces relying on
# single-block aesni_encrypt, which is not the most optimal way to go.
# CBC encrypt result is unexpectedly high and there is no documented
# explanation for it. Seemingly there is a small penalty for feeding
# the result back to AES unit the way it's done in CBC mode. There is
# nothing one can do and the result appears optimal. CCM result is
# identical to CBC, because CBC-MAC is essentially CBC encrypt without
# saving output. CCM CTR "stays invisible," because it's neatly
# interleaved wih CBC-MAC. This provides ~30% improvement over
# "straghtforward" CCM implementation with CTR and CBC-MAC performed
# disjointly. Parallelizable modes practically achieve the theoretical
# limit.
#
# Looking at how results vary with buffer size.
#
```

```
# Curves are practically saturated at 1-KB buffer size. In most cases
# "256-byte" performance is >95%, and "64-byte" is ~90% of "8-KB" one.
# CTR curve doesn't follow this pattern and is "slowest" changing one
# with "256-byte" result being 87% of "8-KB." This is because overhead
# in CTR mode is most computationally intensive. Small-block CCM
# decrypt is slower than encrypt, because first CTR and last CBC-MAC
# iterations can't be interleaved.
#
# Results for 192- and 256-bit keys.
#
# EVP-free results were observed to scale perfectly with number of
# rounds for larger block sizes, i.e. 192-bit result being 10/12 times
# lower and 256-bit one - 10/14. Well, in CBC encrypt case differences
# are a tad smaller, because the above mentioned penalty biases all
# results by same constant value. In similar way function call
# overhead affects small-block performance, as well as OFB and CFB
# results. Differences are not large, most common coefficients are
# 10/11.7 and 10/13.4 (as opposite to 10/12.0 and 10/14.0), but one
# observe even 10/11.2 and 10/12.4 (CTR, OFB, CFB)...

# January 2011
#
# While Westmere processor features 6 cycles latency for aes[enc|dec]
# instructions, which can be scheduled every second cycle, Sandy
# Bridge spends 8 cycles per instruction, but it can schedule them
# every cycle. This means that code targeting Westmere would perform
# suboptimally on Sandy Bridge. Therefore this update.
#
# In addition, non-parallelizable CBC encrypt (as well as CCM) is
# optimized. Relative improvement might appear modest, 8% on Westmere,
# but in absolute terms it's 3.77 cycles per byte encrypted with
# 128-bit key on Westmere, and 5.07 - on Sandy Bridge. These numbers
# should be compared to asymptotic limits of 3.75 for Westmere and
# 5.00 for Sandy Bridge. Actually, the fact that they get this close
# to asymptotic limits is quite amazing. Indeed, the limit is
# calculated as latency times number of rounds, 10 for 128-bit key,
# and divided by 16, the number of bytes in block, or in other words
# it accounts *solely* for aesenc instructions. But there are extra
# instructions, and numbers so close to the asymptotic limits mean
# that it's as if it takes as little as *one* additional cycle to
# execute all of them. How is it possible? It is possible thanks to
# out-of-order execution logic, which manages to overlap post-
# processing of previous block, things like saving the output, with
# actual encryption of current block, as well as pre-processing of
# current block, things like fetching input and xor-ing it with
# 0-round element of the key schedule, with actual encryption of
# previous block. Keep this in mind...
#
# For parallelizable modes, such as ECB, CBC decrypt, CTR, higher
# performance is achieved by interleaving instructions working on
# independent blocks. In which case asymptotic limit for such modes
# can be obtained by dividing above mentioned numbers by AES
# instructions' interleave factor. Westmere can execute at most 3
# instructions at a time, meaning that optimal interleave factor is 3,
# and that's where the "magic" number of 1.25 come from. "Optimal
# interleave factor" means that increase of interleave factor does
# not improve performance. The formula has proven to reflect reality
# pretty well on Westmere... Sandy Bridge on the other hand can
# execute up to 8 AES instructions at a time, so how does varying
# interleave factor affect the performance? Here is table for ECB
# (numbers are cycles per byte processed with 128-bit key):
#
# instruction interleave factor         3x      6x      8x
# theoretical asymptotic limit          1.67    0.83    0.625
# measured performance for 8KB block    1.05    0.86    0.84
#
```

```
# "as if" interleave factor             4.7x    5.8x    6.0x
#
# Further data for other parallelizable modes:
#
# CBC decrypt                           1.16    0.93    0.93
# CTR                                   1.14    0.91    n/a
#
# Well, given 3x column it’s probably inappropriate to call the limit
# asymptotic, if it can be surpassed, isn’t it? What happens there?
# Rewind to CBC paragraph for the answer. Yes, out-of-order execution
# magic is responsible for this. Processor overlaps not only the
# additional instructions with AES ones, but even AES instuctions
# processing adjacent triplets of independent blocks. In the 6x case
# additional instructions  still claim disproportionally small amount
# of additional cycles, but in 8x case number of instructions must be
# a tad too high for out-of-order logic to cope with, and AES unit
# remains underutilized... As you can see 8x interleave is hardly
# justifiable, so there no need to feel bad that 32-bit aesni-x86.pl
# utilizies 6x interleave because of limited register bank capacity.
#
# Higher interleave factors do have negative impact on Westmere
# performance. While for ECB mode it’s negligible ~1.5%, other
# parallelizables perform ~5% worse, which is outweighed by ~25%
# improvement on Sandy Bridge. To balance regression on Westmere
# CTR mode was implemented with 6x aesenc interleave factor.

# April 2011
#
# Add aesni_xts_[en|de]crypt. Westmere spends 1.33 cycles processing
# one byte out of 8KB with 128-bit key, Sandy Bridge - 0.97. Just like
# in CTR mode AES instruction interleave factor was chosen to be 6x.

# _aesni_[en|de]cryptN are private interfaces, N denotes interleave
# factor. Why 3x subroutine were originally used in loops? Even though
# aes[enc|dec] latency was originally 6, it could be scheduled only
# every *2nd* cycle. Thus 3x interleave was the one providing optimal
# utilization, i.e. when subroutine's throughput is virtually same as
# of non-interleaved subroutine [for number of input blocks up to 3].
# This is why it makes no sense to implement 2x subroutine.
# aes[enc|dec] latency in next processor generation is 8, but the
# instructions can be scheduled every cycle. Optimal interleave for
# new processor is therefore 8x...

######################################################################
#
# September 2011.
#
# Started as transliteration to "perlasm" the original code has
# undergone following changes:
#
# - code was made position-independent;
# - rounds were folded into a loop resulting in >5x size reduction
#   from 12.5KB to 2.2KB;
# - above was possibile thanks to mixcolumns() modification that
#   allowed to feed its output back to aesenc[last], this was
#   achieved at cost of two additional inter-registers moves;
# - some instruction reordering and interleaving;
# - this module doesn't implement key setup subroutine, instead it
#   relies on conversion of "conventional" key schedule as returned
#   by AES_set_encrypt_key (see discussion below);
# - first and last round keys are treated differently, which allowed
#   to skip one shiftrows(), reduce bit-sliced key schedule and
#   speed-up conversion by 22%;
# - support for 192- and 256-bit keys was added;
#
# Resulting performance in CPU cycles spent to encrypt one byte out
# of 4096-byte buffer with 128-bit key is:
#
#               Emilia's        this(*)         difference
#
# Core 2        9.30            8.69            +7%
# Nehalem(**)   7.63            6.98            +9%
# Atom          17.1            17.4            -2%(***)
#
# (*)   Comparison is not completely fair, because "this" is ECB,
#       i.e. no extra processing such as counter values calculation
#       and xor-ing input as in Emilia's CTR implementation is
#       performed. However, the CTR calculations stand for not more
#       than 1% of total time, so comparison is *rather* fair.
#
# (**)  Results were collected on Westmere, which is considered to
#       be equivalent to Nehalem for this code.
#
# (***) Slowdown on Atom is rather strange per se, because original
#       implementation has a number of 9+-bytes instructions, which
#       are bad for Atom front-end, and which I eliminated completely.
#       In attempt to address deterioration sbox() was tested in FP
#       SIMD "domain" (movaps instead of movdqa, xorps instead of
#       pxor, etc.). While it resulted in nominal 4% improvement on
#       Atom, it hurted Westmere by more than 2x factor.
#
# As for key schedule conversion subroutine. Interface to OpenSSL
```

```
# relies on per-invocation on-the-fly conversion. This naturally
# has impact on performance, especially for short inputs. Conversion
# time in CPU cycles and its ratio to CPU cycles spent in 8x block
# function is:
#
#               conversion      conversion/8x block
# Core 2        240             0.22
# Nehalem       180             0.20
# Atom          430             0.19
#
# The ratio values mean that 128-byte blocks will be processed
# 16-18% slower, 256-byte blocks - 9-10%, 384-byte blocks - 6-7%,
# etc. Then keep in mind that input sizes not divisible by 128 are
# *effectively* slower, especially shortest ones, e.g. consecutive
# 144-byte blocks are processed 44% slower than one would expect,
# 272 - 29%, 400 - 22%, etc. Yet, despite all these "shortcomings"
# it's still faster than ["hyper-threading-safe" code path in]
# aes-x86_64.pl on all lengths above 64 bytes...
#
# October 2011.
#
# Add decryption procedure. Performance in CPU cycles spent to decrypt
# one byte out of 4096-byte buffer with 128-bit key is:
#
# Core 2        9.83
# Nehalem       7.74
# Atom          19.0
#
# November 2011.
#
# Add bsaes_xts_[en|de]crypt. Less-than-80-bytes-block performance is
# suboptimal, but XTS is meant to be used with larger blocks...
#
#                                               <appro@openssl.org>

  28 # Pairs of numbers in "+" rows represent performance improvement over
  29 # compiler generated position-independent code, PIC, and non-PIC
  30 # respectively. PIC results are of greater relevance, as this module
  31 # is position-independent, i.e. suitable for a shared library or PIE.
  32 # Position independence "costs" one register, which is why compilers
  33 # are so close with non-PIC results, they have an extra register to
  34 # spare. CBC results are better than ECB ones thanks to "zero-copy"
  35 # private _x86_* interface, and are ~30-40% better than with compiler
  36 # generated cmll_cbc.o, and reach ~80-90% of x86_64 performance on
  37 # same CPU (where applicable).

# Performance in cycles per processed byte (less is better) in
# 'openssl speed ...' benchmark:
#
#                       AMD64   Core2   EM64T
# -evp camellia-128-ecb 16.7    21.0    22.7
# + over gcc 3.4.6      +25%    +5%     0%
#
# camellia-128-cbc      15.7    20.4    21.1
#
# 128-bit key setup     128     216     205     cycles/key
# + over gcc 3.4.6      +54%    +39%    +15%
#
# Numbers in "+" rows represent performance improvement over compiler
# generated code. Key setup timings are impressive on AMD and Core2
# thanks to 64-bit operations being covertly deployed. Improvement on
# EM64T, pre-Core2 Intel x86_64 CPU, is not as impressive, because it
# apparently emulates some of 64-bit operations in [32-bit] microcode.

  3 # ====================================================================
  4 # Written by Andy Polyakov <appro@openssl.org> for the OpenSSL
  5 # project. The module is, however, dual licensed under OpenSSL and
  6 # CRYPTOGAMS licenses depending on where you obtain it. For further
  7 # details see http://www.openssl.org/~appro/cryptogams/.
  8 # ====================================================================
  9 #
 10 # March, May, June 2010
 11 #
 12 # The module implements "4-bit" GCM GHASH function and underlying
 13 # single multiplication operation in GF(2^128). "4-bit" means that it
 14 # uses 256 bytes per-key table [+64/128 bytes fixed table]. It has two
 15 # code paths: vanilla x86 and vanilla MMX. Former will be executed on
 16 # 486 and Pentium, latter on all others. MMX GHASH features so called
 17 # "528B" variant of "4-bit" method utilizing additional 256+16 bytes
 18 # of per-key storage [+512 bytes shared table]. Performance results
 19 # are for streamed GHASH subroutine and are expressed in cycles per
 20 # processed byte, less is better:
 21 #
 22 #               gcc 2.95.3(*)   MMX assembler   x86 assembler
 23 #
 24 # Pentium       105/111(**)     -               50
 25 # PIII          68 /75          12.2            24
 26 # P4            125/125         17.8            84(***)
 27 # Opteron       66 /70          10.1            30
 28 # Core2         54 /67          8.4             18
 29 #
 30 # (*)   gcc 3.4.x was observed to generate few percent slower code,
 31 #       which is one of reasons why 2.95.3 results were chosen,
 32 #       another reason is lack of 3.4.x results for older CPUs;
 33 #       comparison with MMX results is not completely fair, because C
 34 #       results are for vanilla "256B" implementation, while
 35 #       assembler results are for "528B";-)
 36 # (**)  second number is result for code compiled with -fPIC flag,
 37 #       which is actually more relevant, because assembler code is
 38 #       position-independent;
 39 # (***) see comment in non-MMX routine for further details;
 40 #
 41 # To summarize, it's >2-5 times faster than gcc-generated code. To
 42 # anchor it to something else SHA1 assembler processes one byte in
 43 # 11-13 cycles on contemporary x86 cores. As for choice of MMX in
 44 # particular, see comment at the end of the file...

 46 # May 2010
 47 #
 48 # Add PCLMULQDQ version performing at 2.10 cycles per processed byte.
 49 # The question is how close is it to theoretical limit? The pclmulqdq
 50 # instruction latency appears to be 14 cycles and there can't be more
 51 # than 2 of them executing at any given time. This means that single
 52 # Karatsuba multiplication would take 28 cycles *plus* few cycles for
 53 # pre- and post-processing. Then multiplication has to be followed by
 54 # modulo-reduction. Given that aggregated reduction method [see
 55 # "Carry-less Multiplication and Its Usage for Computing the GCM Mode"
 56 # white paper by Intel] allows you to perform reduction only once in
 57 # a while we can assume that asymptotic performance can be estimated
 58 # as (28+Tmod/Naggr)/16, where Tmod is time to perform reduction
 59 # and Naggr is the aggregation factor.
 60 #
 61 # Before we proceed to this implementation let's have closer look at
```

```
 62 # the best-performing code suggested by Intel in their white paper.
 63 # By tracing inter-register dependencies Tmod is estimated as ~19
 64 # cycles and Naggr chosen by Intel is 4, resulting in 2.05 cycles per
 65 # processed byte. As implied, this is quite optimistic estimate,
 66 # because it does not account for Karatsuba pre- and post-processing,
 67 # which for a single multiplication is ~5 cycles. Unfortunately Intel
 68 # does not provide performance data for GHASH alone. But benchmarking
 69 # AES_GCM_encrypt ripped out of Fig. 15 of the white paper with aadt
 70 # alone resulted in 2.46 cycles per byte of out 16KB buffer. Note that
 71 # the result accounts even for pre-computing of degrees of the hash
 72 # key H, but its portion is negligible at 16KB buffer size.
 73 #
 74 # Moving on to the implementation in question. Tmod is estimated as
 75 # ~13 cycles and Naggr is 2, giving asymptotic performance of ...
 76 # 2.16. How is it possible that measured performance is better than
 77 # optimistic theoretical estimate? There is one thing Intel failed
 78 # to recognize. By serializing GHASH with CTR in same subroutine
 79 # former's performance is really limited to above (Tmul + Tmod/Naggr)
 80 # equation. But if GHASH procedure is detached, the modulo-reduction
 81 # can be interleaved with Naggr-1 multiplications at instruction level
 82 # and under ideal conditions even disappear from the equation. So that
 83 # optimistic theoretical estimate for this implementation is ...
 84 # 28/16=1.75, and not 2.16. Well, it's probably way too optimistic,
 85 # at least for such small Naggr. I'd argue that (28+Tproc/Naggr),
 86 # where Tproc is time required for Karatsuba pre- and post-processing,
 87 # is more realistic estimate. In this case it gives ... 1.91 cycles.
 88 # Or in other words, depending on how well we can interleave reduction
 89 # and one of the two multiplications the performance should be betwen
 90 # 1.91 and 2.16. As already mentioned, this implementation processes
 91 # one byte out of 8KB buffer in 2.10 cycles, while x86_64 counterpart
 92 # - in 2.02. x86_64 performance is better, because larger register
 93 # bank allows to interleave reduction and multiplication better.
 94 #
 95 # Does it make sense to increase Naggr? To start with it's virtually
 96 # impossible in 32-bit mode, because of limited register bank
 97 # capacity. Otherwise improvement has to be weighed agiainst slower
 98 # setup, as well as code size and complexity increase. As even
 99 # optimistic estimate doesn't promise 30% performance improvement,
100 # there are currently no plans to increase Naggr.
101 #
102 # Special thanks to David Woodhouse <dwmw2@infradead.org> for
103 # providing access to a Westmere-based system on behalf of Intel
104 # Open Source Technology Centre.

106 # January 2010
107 #
108 # Tweaked to optimize transitions between integer and FP operations
109 # on same XMM register, PCLMULQDQ subroutine was measured to process
110 # one byte in 2.07 cycles on Sandy Bridge, and in 2.12 - on Westmere.
111 # The minor regression on Westmere is outweighed by ~15% improvement
112 # on Sandy Bridge. Strangely enough attempt to modify 64-bit code in
113 # similar manner resulted in almost 20% degradation on Sandy Bridge,
114 # where original 64-bit code processes one byte in 1.95 cycles.

&asciz("GHASH for x86, CRYPTOGAMS by <appro\@openssl.org>");
&asm_finish();

# A question was risen about choice of vanilla MMX. Or rather why wasn't
# SSE2 chosen instead? In addition to the fact that MMX runs on legacy
# CPUs such as PIII, "4-bit" MMX version was observed to provide better
# performance than *corresponding* SSE2 one even on contemporary CPUs.
# SSE2 results were provided by Peter-Michael Hager. He maintains SSE2
# implementation featuring full range of lookup-table sizes, but with
# per-invocation lookup table setup. Latter means that table size is
# chosen depending on how much data is to be hashed in every given call,
# more data - larger table. Best reported result for Core2 is ~4 cycles
# per processed byte out of 64KB block. This number accounts even for
# 64KB table setup overhead. As discussed in gcm128.c we choose to be
# more conservative in respect to lookup table sizes, but how do the
# results compare? Minimalistic "256B" MMX version delivers ~11 cycles
# on same platform. As also discussed in gcm128.c, next in line "8-bit
# Shoup's" or "4KB" method should deliver twice the performance of
# "256B" one, in other words not worse than ~6 cycles per byte. It
# should be also be noted that in SSE2 case improvement can be "super-
# linear," i.e. more than twice, mostly because >>8 maps to single
```

```
# instruction on SSE2 register. This is unlike "4-bit" case when >>4
# maps to same amount of instructions in both MMX and SSE2 cases.
# Bottom line is that switch to SSE2 is considered to be justifiable
# only in case we choose to implement "8-bit" method...
#endif /* ! codereview */
```

# ====================================================================
# Written by Andy Polyakov <appro@openssl.org> for the OpenSSL
# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================
#
# March, June 2010
#
# The module implements "4-bit" GCM GHASH function and underlying
# single multiplication operation in GF(2^128). "4-bit" means that
# it uses 256 bytes per-key table [+128 bytes shared table]. GHASH
# function features so called "528B" variant utilizing additional
# 256+16 bytes of per-key storage [+512 bytes shared table].
# Performance results are for this streamed GHASH subroutine and are
# expressed in cycles per processed byte, less is better:
#
#               gcc 3.4.x(*)    assembler
#
# P4            28.6            14.0            +100%
# Opteron       19.3            7.7             +150%
# Core2         17.8            8.1(**)         +120%
#
# (*)   comparison is not completely fair, because C results are
#       for vanilla "256B" implementation, while assembler results
#       are for "528B";-)
# (**)  it's mystery [to me] why Core2 result is not same as for
#       Opteron;

# May 2010
#
# Add PCLMULQDQ version performing at 2.02 cycles per processed byte.
# See ghash-x86.pl for background information and details about coding
# techniques.
#
# Special thanks to David Woodhouse <dwmw2@infradead.org> for
# providing access to a Westmere-based system on behalf of Intel
# Open Source Technology Centre.

# ====================================================================
# [Re]written by Andy Polyakov <appro@fy.chalmers.se> for the OpenSSL
# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================

# At some point it became apparent that the original SSLeay RC4
# assembler implementation performs suboptimally on latest IA-32
# microarchitectures. After re-tuning performance has changed as
# following:
#
# Pentium       -10%
# Pentium III   +12%
# AMD           +50%(*)
# P4            +250%(**)
#
# (*)   This number is actually a trade-off:-) It's possible to
#       achieve +72%, but at the cost of -48% off PIII performance.
#       In other words code performing further 13% faster on AMD
#       would perform almost 2 times slower on Intel PIII...
#       For reference! This code delivers ~80% of rc4-amd64.pl
#       performance on the same Opteron machine.
# (**)  This number requires compressed key schedule set up by
#       RC4_set_key [see commentary below for further details].
#
#                                       <appro@fy.chalmers.se>

# May 2011
#
# Optimize for Core2 and Westmere [and incidentally Opteron]. Current
# performance in cycles per processed byte (less is better) and
# improvement relative to previous version of this module is:
#
# Pentium       10.2                    # original numbers
# Pentium III   7.8(*)
# Intel P4      7.5
#
# Opteron       6.1/+20%                # new MMX numbers
# Core2         5.3/+67%(**)
# Westmere      5.1/+94%(**)
# Sandy Bridge  5.0/+8%
# Atom          12.6/+6%
#
# (*)   PIII can actually deliver 6.6 cycles per byte with MMX code,
#       but this specific code performs poorly on Core2. And vice
#       versa, below MMX/SSE code delivering 5.8/7.1 on Core2 performs
#       poorly on PIII, at 8.0/14.5:-( As PIII is not a "hot" CPU
#       [anymore], I chose to discard PIII-specific code path and opt
#       for original IALU-only code, which is why MMX/SSE code path
#       is guarded by SSE2 bit (see below), not MMX/SSE.
# (**)  Performance vs. block size on Core2 and Westmere had a maximum
#       at ... 64 bytes block size. And it was quite a maximum, 40-60%
#       in comparison to largest 8KB block size. Above improvement
#       coefficients are for the largest block size.

# June 2011
#
# This is RC4+MD5 "stitch" implementation. The idea, as spelled in
# http://download.intel.com/design/intarch/papers/323686.pdf, is that
# since both algorithms exhibit instruction-level parallelism, ILP,
# below theoretical maximum, interleaving them would allow to utilize
# processor resources better and achieve better performance. RC4
# instruction sequence is virtually identical to rc4-x86_64.pl, which
# is heavily based on submission by Maxim Perminov, Maxim Locktyukhin
# and Jim Guilford of Intel. MD5 is fresh implementation aiming to
# minimize register usage, which was used as "main thread" with RC4
# weaved into it, one RC4 round per one MD5 round. In addition to the
# stiched subroutine the script can generate standalone replacement
# md5_block_asm_data_order and RC4. Below are performance numbers in
# cycles per processed byte, less is better, for these the standalone
# subroutines, sum of them, and stitched one:
#
#               RC4     MD5     RC4+MD5 stitch  gain
# Opteron       6.5(*)  5.4     11.9    7.0     +70%(*)
# Core2         6.5     5.8     12.3    7.7     +60%
# Westmere      4.3     5.2     9.5     7.0     +36%
# Sandy Bridge  4.2     5.5     9.7     6.8     +43%
# Atom          9.3     6.5     15.8    11.1    +42%
#
# (*)   rc4-x86_64.pl delivers 5.3 on Opteron, so real improvement
#       is +53%...

my ($rc4,$md5)=(1,1);   # what to generate?
my $D="#" if (!$md5);   # if set to "#", MD5 is stitched into RC4(),
                        # but its result is discarded. Idea here is
                        # to be able to use 'openssl speed rc4' for
                        # benchmarking the stitched subroutine...

#
# ====================================================================
# Written by Andy Polyakov <appro@fy.chalmers.se> for the OpenSSL
# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================
#
# July 2004
#
# 2.22x RC4 tune-up:-) It should be noted though that my hand [as in
# "hand-coded assembler"] doesn't stand for the whole improvement
# coefficient. It turned out that eliminating RC4_CHAR from config
# line results in ~40% improvement (yes, even for C implementation).
# Presumably it has everything to do with AMD cache architecture and
# RAW or whatever penalties. Once again! The module *requires* config
# line *without* RC4_CHAR! As for coding "secret," I bet on partial
# register arithmetics. For example instead of 'inc %r8; and $255,%r8'
# I simply 'inc %r8b'. Even though optimization manual discourages
# to operate on partial registers, it turned out to be the best bet.
# At least for AMD... How IA32E would perform remains to be seen...

# November 2004
#
# As was shown by Marc Bevand reordering of couple of load operations
# results in even higher performance gain of 3.3x:-) At least on
# Opteron... For reference, 1x in this case is RC4_CHAR C-code
# compiled with gcc 3.3.2, which performs at ~54MBps per 1GHz clock.
# Latter means that if you want to *estimate* what to expect from
# *your* Opteron, then multiply 54 by 3.3 and clock frequency in GHz.

# November 2004
#
# Intel P4 EM64T core was found to run the AMD64 code really slow...
# The only way to achieve comparable performance on P4 was to keep
# RC4_CHAR. Kind of ironic, huh? As it's apparently impossible to
# compose blended code, which would perform even within 30% marginal
# on either AMD and Intel platforms, I implement both cases. See
# rc4_skey.c for further details...

# April 2005
#
# P4 EM64T core appears to be "allergic" to 64-bit inc/dec. Replacing
# those with add/sub results in 50% performance improvement of folded
# loop...

# May 2005
#
# As was shown by Zou Nanhai loop unrolling can improve Intel EM64T
# performance by >30% [unlike P4 32-bit case that is]. But this is
# provided that loads are reordered even more aggressively! Both code
# pathes, AMD64 and EM64T, reorder loads in essentially same manner
# as my IA-64 implementation. On Opteron this resulted in modest 5%
# improvement [I had to test it], while final Intel P4 performance
# achieves respectful 432MBps on 2.8GHz processor now. For reference.
# If executed on Xeon, current RC4_CHAR code-path is 2.7x faster than
# RC4_INT code-path. While if executed on Opteron, it's only 25%
# slower than the RC4_INT one [meaning that if CPU µ-arch detection
# is not implemented, then this final RC4_CHAR code-path should be
# preferred, as it provides better *all-round* performance].
```

```
# March 2007
#
# Intel Core2 was observed to perform poorly on both code paths:-( It
# apparently suffers from some kind of partial register stall, which
# occurs in 64-bit mode only [as virtually identical 32-bit loop was
# observed to outperform 64-bit one by almost 50%]. Adding two movzb to
# cloop1 boosts its performance by 80%! This loop appears to be optimal
# fit for Core2 and therefore the code was modified to skip cloop8 on
# this CPU.

# May 2010
#
# Intel Westmere was observed to perform suboptimally. Adding yet
# another movzb to cloop1 improved performance by almost 50%! Core2
# performance is improved too, but nominally...

# May 2011
#
# The only code path that was not modified is P4-specific one. Non-P4
# Intel code path optimization is heavily based on submission by Maxim
# Perminov, Maxim Locktyukhin and Jim Guilford of Intel. I've used
# some of the ideas even in attempt to optmize the original RC4_INT
# code path... Current performance in cycles per processed byte (less
# is better) and improvement coefficients relative to previous
# version of this module are:
#
# Opteron       5.3/+0%(*)
# P4            6.5
# Core2         6.2/+15%(**)
# Westmere      4.2/+60%
# Sandy Bridge  4.2/+120%
# Atom          9.3/+80%
#
# (*)   But corresponding loop has less instructions, which should have
#       positive effect on upcoming Bulldozer, which has one less ALU.
#       For reference, Intel code runs at 6.8 cpb rate on Opteron.
# (**)  Note that Core2 result is ~15% lower than corresponding result
#       for 32-bit code, meaning that it's possible to improve it,
#       but more than likely at the cost of the others (see rc4-586.pl
#       to get the idea)...

#!/usr/bin/env perl

# ====================================================================
# [Re]written by Andy Polyakov <appro@fy.chalmers.se> for the OpenSSL
# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================

# "[Re]written" was achieved in two major overhauls. In 2004 BODY_*
# functions were re-implemented to address P4 performance issue [see
# commentary below], and in 2006 the rest was rewritten in order to
# gain freedom to liberate licensing terms.

# January, September 2004.
#
# It was noted that Intel IA-32 C compiler generates code which
# performs ~30% *faster* on P4 CPU than original *hand-coded*
# SHA1 assembler implementation. To address this problem (and
# prove that humans are still better than machines:-), the
# original code was overhauled, which resulted in following
# performance changes:
#
#               compared with original  compared with Intel cc
#               assembler impl.         generated code
# Pentium       -16%                    +48%
# PIII/AMD      +8%                     +16%
# P4            +85%(!)                 +45%
#
# As you can see Pentium came out as looser:-( Yet I reckoned that
# improvement on P4 outweights the loss and incorporate this
# re-tuned code to 0.9.7 and later.
# ----------------------------------------------------------------
#                                       <appro@fy.chalmers.se>

# August 2009.
#
# George Spelvin has tipped that F_40_59(b,c,d) can be rewritten as
# '(c&d) + (b&(c^d))', which allows to accumulate partial results
# and lighten "pressure" on scratch registers. This resulted in
# >12% performance improvement on contemporary AMD cores (with no
# degradation on other CPUs:-). Also, the code was revised to maximize
# "distance" between instructions producing input to 'lea' instruction
# and the 'lea' instruction itself, which is essential for Intel Atom
# core and resulted in ~15% improvement.

# October 2010.
#
# Add SSSE3, Supplemental[!] SSE3, implementation. The idea behind it
# is to offload message schedule denoted by Wt in NIST specification,
# or Xupdate in OpenSSL source, to SIMD unit. The idea is not novel,
# and in SSE2 context was first explored by Dean Gaudet in 2004, see
# http://arctic.org/~dean/crypto/sha1.html. Since then several things
# have changed that made it interesting again:
#
# a) XMM units became faster and wider;
# b) instruction set became more versatile;
# c) an important observation was made by Max Locktykhin, which made
#    it possible to reduce amount of instructions required to perform
#    the operation in question, for further details see
#    http://software.intel.com/en-us/articles/improving-the-performance-of-the-s

# April 2011.
#
# Add AVX code path, probably most controversial... The thing is that
# switch to AVX alone improves performance by as little as 4% in
# comparison to SSSE3 code path. But below result doesn't look like
# 4% improvement... Trouble is that Sandy Bridge decodes 'ro[rl]' as
# pair of µ-ops, and it's the additional µ-ops, two per round, that
# make it run slower than Core2 and Westmere. But 'sh[rl]d' is decoded
# as single µ-op by Sandy Bridge and it's replacing 'ro[rl]' with
# equivalent 'sh[rl]d' that is responsible for the impressive 5.1
# cycles per processed byte. But 'sh[rl]d' is not something that used
# to be fast, nor does it appear to be fast in upcoming Bulldozer
# [according to its optimization manual]. Which is why AVX code path
# is guarded by *both* AVX and synthetic bit denoting Intel CPUs.
# One can argue that it's unfair to AMD, but without 'sh[rl]d' it
# makes no sense to keep the AVX code path. If somebody feels that
# strongly, it's probably more appropriate to discuss possibility of
# using vector rotate XOP on AMD...

######################################################################
# Current performance is summarized in following table. Numbers are
# CPU clock cycles spent to process single byte (less is better).
#
#               x86             SSSE3           AVX
# Pentium       15.7            -
# PIII          11.5            -
# P4            10.6            -
# AMD K8        7.1             -
# Core2         7.3             6.1/+20%        -
# Atom          12.5            9.5(*)/+32%     -
# Westmere      7.3             5.6/+30%        -
# Sandy Bridge  8.8             6.2/+40%        5.1(**)/+70%
#
# (*)   Loop is 1056 instructions long and expected result is ~8.25.
#       It remains mystery [to me] why ILP is limited to 1.7.
#
# (**)  As per above comment, the result is for AVX *plus* sh[rl]d.

392 ######################################################################
393 # The SSSE3 implementation.
394 #
395 # %xmm[0-7] are used as ring @X[] buffer containing quadruples of last
396 # 32 elements of the message schedule or Xupdate outputs. First 4
397 # quadruples are simply byte-swapped input, next 4 are calculated
398 # according to method originally suggested by Dean Gaudet (modulo
399 # being implemented in SSSE3). Once 8 quadruples or 32 elements are
400 # collected, it switches to routine proposed by Max Locktyukhin.
401 #
402 # Calculations inevitably require temporary registers, and there are
403 # no %xmm registers left to spare. For this reason part of the ring
404 # buffer, X[2..4] to be specific, is offloaded to 3 quadriples ring
405 # buffer on the stack. Keep in mind that X[2] is alias X[-6], X[3] -
406 # X[-5], and X[4] - X[-4]...
407 #
408 # Another notable optimization is aggressive stack frame compression
409 # aiming to minimize amount of 9-byte instructions...
410 #
411 # Yet another notable optimization is "jumping" $B variable. It means
412 # that there is no register permanently allocated for $B value. This
413 # allowed to eliminate one instruction from body_20_39...
414 #

508 ######################################################################
509 # SSE instruction sequence is first broken to groups of indepentent
510 # instructions, independent in respect to their inputs and shifter
511 # (not all architectures have more than one). Then IALU instructions
512 # are "knitted in" between the SSE groups. Distance is maintained for
513 # SSE latency of 2 in hope that it fits better upcoming AMD Bulldozer
514 # [which allegedly also implements SSSE3]...
515 #
516 # Temporary registers usage. X[2] is volatile at the entry and at the
517 # end is restored from backtrace ring buffer. X[3] is expected to
518 # contain current K_XX_XX constant and is used to caclulate X[-1]+K
519 # from previous round, it becomes volatile the moment the value is
520 # saved to stack for transfer to IALU. X[4] becomes volatile whenever
521 # X[-4] is accumulated and offloaded to backtrace ring buffer, at the
522 # end it is loaded with next K_XX_XX [which becomes X[3] in next
523 # round]...

# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================
#
# sha1_block procedure for x86_64.
#
# It was brought to my attention that on EM64T compiler-generated code
# was far behind 32-bit assembler implementation. This is unlike on
# Opteron where compiler-generated code was only 15% behind 32-bit
# assembler, which originally made it hard to motivate the effort.
# There was suggestion to mechanically translate 32-bit code, but I
# dismissed it, reasoning that x86_64 offers enough register bank
# capacity to fully utilize SHA-1 parallelism. Therefore this fresh
# implementation:-) However! While 64-bit code does perform better
# on Opteron, I failed to beat 32-bit assembler on EM64T core. Well,
# x86_64 does offer larger *addressable* bank, but out-of-order core
# reaches for even more registers through dynamic aliasing, and EM64T
# core must have managed to run-time optimize even 32-bit code just as
# good as 64-bit one. Performance improvement is summarized in the
# following table:
#
#               gcc 3.4         32-bit asm      cycles/byte
# Opteron       +45%            +20%            6.8
# Xeon P4       +65%            +0%             9.9
# Core2         +60%            +10%            7.0

# August 2009.
#
# The code was revised to minimize code size and to maximize
# "distance" between instructions producing input to 'lea'
# instruction and the 'lea' instruction itself, which is essential
# for Intel Atom core.

# October 2010.
#
# Add SSSE3, Supplemental[!] SSE3, implementation. The idea behind it
# is to offload message schedule denoted by Wt in NIST specification,
# or Xupdate in OpenSSL source, to SIMD unit. See sha1-586.pl module
# for background and implementation details. The only difference from
# 32-bit code is that 64-bit code doesn't have to spill @X[] elements
# to free temporary registers.

# April 2011.
#
# Add AVX code path. See sha1-586.pl for further information.

######################################################################
# Current performance is summarized in following table. Numbers are
# CPU clock cycles spent to process single byte (less is better).
#
#               x86_64          SSSE3           AVX
# P4            9.8             -
# Opteron       6.6             -
# Core2         6.7             6.1/+10%        -
# Atom          11.0            9.7/+13%        -
# Westmere      7.1             5.6/+27%        -
```

```
# Sandy Bridge  7.9             6.3/+25%        5.2/+51%

#
# SHA256 block transform for x86. September 2007.
#
# Performance in clock cycles per processed byte (less is better):
#
#               Pentium PIII    P4      AMD K8  Core2
# gcc           46      36      41      27      26
# icc           57      33      38      25      23
# x86 asm       40      30      33      20      18
# x86_64 asm(*) -       -       21      16      16
#
# (*) x86_64 assembler performance is presented for reference
#     purposes.
#
# Performance improvement over compiler generated code varies from
# 10% to 40% [see above]. Not very impressive on some µ-archs, but
# it's 5 times smaller and optimizies amount of writes.

#
# SHA512 block transform for x86. September 2007.
#
# Performance in clock cycles per processed byte (less is better):
#
#               Pentium PIII    P4      AMD K8  Core2
# gcc           100     75      116     54      66
# icc           97      77      95      55      57
# x86 asm       61      56      82      36      40
# SSE2 asm      -       -       38      24      20
# x86_64 asm(*) -       -       30      10.0    10.5
#
# (*) x86_64 assembler performance is presented for reference
#     purposes.
#
# IALU code-path is optimized for elder Pentiums. On vanilla Pentium
# performance improvement over compiler generated code reaches ~60%,
# while on PIII - ~35%. On newer µ-archs improvement varies from 15%
# to 50%, but it's less important as they are expected to execute SSE2
# code-path, which is commonly ~2-3x faster [than compiler generated
# code]. SSE2 code-path is as fast as original sha512-sse2.pl, even
# though it does not use 128-bit operations. The latter means that
# SSE2-aware kernel is no longer required to execute the code. Another
# difference is that new code optimizes amount of writes, but at the
# cost of increased data cache "footprint" by 1/2KB.

#
# sha256/512_block procedure for x86_64.
#
# 40% improvement over compiler-generated code on Opteron. On EM64T
# sha256 was observed to run >80% faster and sha512 - >40%. No magical
# tricks, just straight implementation... I really wonder why gcc
# [being armed with inline assembler] fails to generate as fast code.
# The only thing which is cool about this module is that it's very
# same instruction sequence used for both SHA-256 and SHA-512. In
# former case the instructions operate on 32-bit operands, while in
# latter - on 64-bit ones. All I had to do is to get one flavor right,
# the other one passed the test right away:-)
#
# sha256_block runs in ~1005 cycles on Opteron, which gives you
# asymptotic performance of 64*1000/1005=63.7MBps times CPU clock
# frequency in GHz. sha512_block runs in ~1275 cycles, which results
# in 128*1000/1275=100MBps per GHz. Is there room for improvement?
# Well, if you compare it to IA-64 implementation, which maintains
# X[16] in register bank[!], tends to 4 instructions per CPU clock
# cycle and runs in 1003 cycles, 1275 is very good result for 3-way
# issue Opteron pipeline and X[16] maintained in memory. So that *if*
# there is a way to improve it, *then* the only way would be to try to
# offload X[16] updates to SSE unit, but that would require "deeper"
# loop unroll, which in turn would naturally cause size blow-up, not
# to mention increased complexity! And once again, only *if* it's
# actually possible to noticeably improve overall ILP, instruction
# level parallelism, on a given CPU implementation in this case.
#
# Special note on Intel EM64T. While Opteron CPU exhibits perfect
# perfromance ratio of 1.5 between 64- and 32-bit flavors [see above],
# [currently available] EM64T CPUs apparently are far from it. On the
# contrary, 64-bit version, sha512_block, is ~30% *slower* than 32-bit
# sha256_block:-( This is presumably because 64-bit shifts/rotates
# apparently are not atomic instructions, but implemented in microcode.

######################################################################
## Constant-time SSSE3 AES core implementation.
## version 0.1
##
## By Mike Hamburg (Stanford University), 2009
## Public domain.
##
## For details see http://shiftleft.org/papers/vector_aes/ and
## http://crypto.stanford.edu/vpaes/.

######################################################################
# September 2011.
#
# Port vpaes-x86_64.pl as 32-bit "almost" drop-in replacement for
# aes-586.pl. "Almost" refers to the fact that AES_cbc_encrypt
# doesn't handle partial vectors (doesn't have to if called from
# EVP only). "Drop-in" implies that this module doesn't share key
# schedule structure with the original nor does it make assumption
# about its alignment...
#
# Performance summary. aes-586.pl column lists large-block CBC
# encrypt/decrypt/with-hyper-threading-off(*) results in cycles per
# byte processed with 128-bit key, and vpaes-x86.pl column - [also
# large-block CBC] encrypt/decrypt.
#
#               aes-586.pl              vpaes-x86.pl
#
# Core 2(**)    29.1/42.3/18.3          22.0/25.6(***)
# Nehalem       27.9/40.4/18.1          10.3/12.0
# Atom          102./119./60.1          64.5/85.3(***)
#
# (*)   "Hyper-threading" in the context refers rather to cache shared
#       among multiple cores, than to specifically Intel HTT. As vast
#       majority of contemporary cores share cache, slower code path
#       is common place. In other words "with-hyper-threading-off"
#       results are presented mostly for reference purposes.
#
# (**)  "Core 2" refers to initial 65nm design, a.k.a. Conroe.
#
# (***) Less impressive improvement on Core 2 and Atom is due to slow
#       pshufb, yet it's respectable +32%/65%  improvement on Core 2
#       and +58%/40% on Atom (as implied, over "hyper-threading-safe"
#       code path).
#
#                                               <appro@openssl.org>

## Constant-time SSSE3 AES core implementation.
## version 0.1
##
## By Mike Hamburg (Stanford University), 2009
## Public domain.
##
## For details see http://shiftleft.org/papers/vector_aes/ and
## http://crypto.stanford.edu/vpaes/.

######################################################################
# September 2011.
#
# Interface to OpenSSL as "almost" drop-in replacement for
# aes-x86_64.pl. "Almost" refers to the fact that AES_cbc_encrypt
# doesn't handle partial vectors (doesn't have to if called from
# EVP only). "Drop-in" implies that this module doesn't share key
# schedule structure with the original nor does it make assumption
# about its alignment...
#
# Performance summary. aes-x86_64.pl column lists large-block CBC
# encrypt/decrypt/with-hyper-threading-off(*) results in cycles per
# byte processed with 128-bit key, and vpaes-x86_64.pl column -
# [also large-block CBC] encrypt/decrypt.
#
#               aes-x86_64.pl           vpaes-x86_64.pl
#
# Core 2(**)    30.5/43.7/14.3          21.8/25.7(***)
# Nehalem       30.5/42.2/14.6           9.8/11.8
# Atom          63.9/79.0/32.1          64.0/84.8(***)
#
# (*)   "Hyper-threading" in the context refers rather to cache shared
#       among multiple cores, than to specifically Intel HTT. As vast
#       majority of contemporary cores share cache, slower code path
#       is common place. In other words "with-hyper-threading-off"
#       results are presented mostly for reference purposes.
#
# (**)  "Core 2" refers to initial 65nm design, a.k.a. Conroe.
#
# (***) Less impressive improvement on Core 2 and Atom is due to slow
#       pshufb, yet it's respectable +40%/78% improvement on Core 2
#       (as implied, over "hyper-threading-safe" code path).
#
#                                               <appro@openssl.org>

##
##  _aes_encrypt_core
##
##  AES-encrypt %xmm0.
##
##  Inputs:
##     %xmm0 = input
##     %xmm9-%xmm15 as in _vpaes_preheat
##    (%rdx) = scheduled keys
##
##  Output in %xmm0
##  Clobbers  %xmm1-%xmm5, %r9, %r10, %r11, %rax
##  Preserves %xmm6 - %xmm8 so you get some local vectors
##
##

336 ##
337 ##  .aes_schedule_192
338 ##
339 ##  192-bit specific part of key schedule.
340 ##
341 ##  The main body of this schedule is the same as the 128-bit
342 ##  schedule, but with more smearing.  The long, high side is
343 ##  stored in %xmm7 as before, and the short, low side is in
344 ##  the high bits of %xmm6.
345 ##
346 ##  This schedule is somewhat nastier, however, because each
347 ##  round produces 192 bits of key material, or 1.5 round keys.
348 ##  Therefore, on each cycle we do 2 rounds and produce 3 round
349 ##  keys.
350 ##

#
# ====================================================================
# Written by Andy Polyakov <appro@openssl.org> for the OpenSSL
# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================
#
# May 2011
#
# The module implements bn_GF2m_mul_2x2 polynomial multiplication used
# in bn_gf2m.c. It's kind of low-hanging mechanical port from C for
# the time being... Except that it has three code paths: pure integer
# code suitable for any x86 CPU, MMX code suitable for PIII and later
# and PCLMULQDQ suitable for Westmere and later. Improvement varies
# from one benchmark and µ-arch to another. Below are interval values
# for 163- and 571-bit ECDH benchmarks relative to compiler-generated
# code:
#
# PIII          16%-30%
# P4            12%-12%
# Opteron       18%-40%
# Core2         19%-44%
# Atom          38%-64%
# Westmere      53%-121%(PCLMULQDQ)/20%-32%(MMX)
# Sandy Bridge  72%-127%(PCLMULQDQ)/27%-23%(MMX)
#
# Note that above improvement coefficients are not coefficients for
# bn_GF2m_mul_2x2 itself. For example 120% ECDH improvement is result
# of bn_GF2m_mul_2x2 being >4x faster. As it gets faster, benchmark
# is more and more dominated by other subroutines, most notably by
# BN_GF2m_mod[_mul]_arr...

# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================

# October 2005
#
# This is a "teaser" code, as it can be improved in several ways...
# First of all non-SSE2 path should be implemented (yes, for now it
# performs Montgomery multiplication/convolution only on SSE2-capable
# CPUs such as P4, others fall down to original code). Then inner loop
# can be unrolled and modulo-scheduled to improve ILP and possibly
# moved to 128-bit XMM register bank (though it would require input
# rearrangement and/or increase bus bandwidth utilization). Dedicated
# squaring procedure should give further performance improvement...
# Yet, for being draft, the code improves rsa512 *sign* benchmark by
# 110%(!), rsa1024 one - by 70% and rsa4096 - by 20%:-)

# December 2006
#
# Modulo-scheduling SSE2 loops results in further 15-20% improvement.
# Integer-only code [being equipped with dedicated squaring procedure]
# gives ~40% on rsa512 sign benchmark...

  3 # ====================================================================
  4 # Written by Andy Polyakov <appro@openssl.org> for the OpenSSL
  5 # project. The module is, however, dual licensed under OpenSSL and
  6 # CRYPTOGAMS licenses depending on where you obtain it. For further
  7 # details see http://www.openssl.org/~appro/cryptogams/.
  8 # ====================================================================
  9 #
 10 # May 2011
 11 #
 12 # The module implements bn_GF2m_mul_2x2 polynomial multiplication used
 13 # in bn_gf2m.c. It's kind of low-hanging mechanical port from C for
 14 # the time being... Except that it has two code paths: code suitable
 15 # for any x86_64 CPU and PCLMULQDQ one suitable for Westmere and
 16 # later. Improvement varies from one benchmark and µ-arch to another.
 17 # Vanilla code path is at most 20% faster than compiler-generated code
 18 # [not very impressive], while PCLMULQDQ - whole 85%-160% better on
 19 # 163- and 571-bit ECDH benchmarks on Intel CPUs. Keep in mind that
 20 # these coefficients are not ones for bn_GF2m_mul_2x2 itself, as not
 21 # all CPU time is burnt in it...

# ====================================================================
# Written by Andy Polyakov <appro@openssl.org> for the OpenSSL
# project. The module is, however, dual licensed under OpenSSL and
# CRYPTOGAMS licenses depending on where you obtain it. For further
# details see http://www.openssl.org/~appro/cryptogams/.
# ====================================================================

# October 2005.
#
# Montgomery multiplication routine for x86_64. While it gives modest
# 9% improvement of rsa4096 sign on Opteron, rsa512 sign runs more
# than twice, >2x, as fast. Most common rsa1024 sign is improved by
# respectful 50%. It remains to be seen if loop unrolling and
# dedicated squaring routine can provide further improvement...

# July 2011.
#
# Add dedicated squaring procedure. Performance improvement varies
# from platform to platform, but in average it's ~5%/15%/25%/33%
# for 512-/1024-/2048-/4096-bit RSA *sign* benchmarks respectively.

# August 2011.
#
# Unroll and modulo-schedule inner loops in such manner that they
# are "fallen through" for input lengths of 8, which is critical for
# 1024-bit RSA *sign*. Average performance improvement in comparison
# to *initial* version of this module from 2005 is ~0%/30%/40%/45%
# for 512-/1024-/2048-/4096-bit RSA *sign* benchmarks respectively.

# August 2011.
#
# Companion to x86_64-mont.pl that optimizes cache-timing attack
# countermeasures. The subroutines are produced by replacing bp[i]
# references in their x86_64-mont.pl counterparts with cache-neutral
# references to powers table computed in BN_mod_exp_mont_consttime.
# In addition subroutine that scatters elements of the powers table
# is implemented, so that scatter-/gathering can be tuned without
# bn_exp.c modifications.

#!/usr/bin/env perl

# Ascetic x86_64 AT&T to MASM/NASM assembler translator by <appro>.
#
# Why AT&T to MASM and not vice versa? Several reasons. Because AT&T
# format is way easier to parse. Because it's simpler to "gear" from
# Unix ABI to Windows one [see cross-reference "card" at the end of
# file]. Because Linux targets were available first...
#
# In addition the script also "distills" code suitable for GNU
# assembler, so that it can be compiled with more rigid assemblers,
# such as Solaris /usr/ccs/bin/as.
#
# This translator is not designed to convert *arbitrary* assembler
# code from AT&T format to MASM one. It's designed to convert just
# enough to provide for dual-ABI OpenSSL modules development...
# There *are* limitations and you might have to modify your assembler
# code or this script to achieve the desired result...
#
# Currently recognized limitations:
#
# - can't use multiple ops per line;
#
# Dual-ABI styling rules.
#
# 1. Adhere to Unix register and stack layout [see cross-reference
#    ABI "card" at the end for explanation].
# 2. Forget about "red zone," stick to more traditional blended
#    stack frame allocation. If volatile storage is actually required
#    that is. If not, just leave the stack as is.
# 3. Functions tagged with ".type name,@function" get crafted with
#    unified Win64 prologue and epilogue automatically. If you want
#    to take care of ABI differences yourself, tag functions as
#    ".type name,@abi-omnipotent" instead.
# 4. To optimize the Win64 prologue you can specify number of input
#    arguments as ".type name,@function,N." Keep in mind that if N is
#    larger than 6, then you *have to* write "abi-omnipotent" code,
#    because >6 cases can't be addressed with unified prologue.
# 5. Name local labels as .L*, do *not* use dynamic labels such as 1:
#    (sorry about latter).
# 6. Don't use [or hand-code with .byte] "rep ret." "ret" mnemonic is
#    required to identify the spots, where to inject Win64 epilogue!
#    But on the pros, it's then prefixed with rep automatically:-)
# 7. Stick to explicit ip-relative addressing. If you have to use
#    GOTPCREL addressing, stick to mov symbol@GOTPCREL(%rip),%r??.
#    Both are recognized and translated to proper Win64 addressing
#    modes. To support legacy code a synthetic directive, .picmeup,
#    is implemented. It puts address of the *next* instruction into
#    target register, e.g.:
#
#               .picmeup        %rax
#               lea             .Label-.(%rax),%rax
#
# 8. In order to provide for structured exception handling unified
#    Win64 prologue copies %rsp value to %rax. For further details
#    see SEH paragraph at the end.
# 9. .init segment is allowed to contain calls to functions only.
# a. If function accepts more than 4 arguments *and* >4th argument
#    is declared as non 64-bit value, do clear its upper part.

883 #
884 # (*)   volatile register
885 # (-)   preserved by callee
886 # (#)   Nth argument, volatile
887 #
888 # In Unix terms top of stack is argument transfer area for arguments
889 # which could not be accomodated in registers. Or in other words 7th
890 # [integer] argument resides at 8(%rsp) upon function entry point.
891 # 128 bytes above %rsp constitute a "red zone" which is not touched
892 # by signal handlers and can be used as temporal storage without
893 # allocating a frame.
894 #
895 # In Win64 terms N*8 bytes on top of stack is argument transfer area,
896 # which belongs to/can be overwritten by callee. N is the number of
897 # arguments passed to callee, *but* not less than 4! This means that
898 # upon function entry point 5th argument resides at 40(%rsp), as well
899 # as that 32 bytes from 8(%rsp) can always be used as temporal
900 # storage [without allocating a frame]. One can actually argue that
901 # one can assume a "red zone" above stack pointer under Win64 as well.
902 # Point is that at apparently no occasion Windows kernel would alter
903 # the area above user stack pointer in true asynchronous manner...
904 #
905 # All the above means that if assembler programmer adheres to Unix
906 # register and stack layout, but disregards the "red zone" existense,
907 # it's possible to use following prologue and epilogue to "gear" from
908 # Unix to Win64 ABI in leaf functions with not more than 6 arguments.
909 #
910 # omnipotent_function:
911 # ifdef WIN64
912 #       movq    %rdi,8(%rsp)
913 #       movq    %rsi,16(%rsp)
914 #       movq    %rcx,%rdi       ; if 1st argument is actually present
915 #       movq    %rdx,%rsi       ; if 2nd argument is actually ...
916 #       movq    %r8,%rdx        ; if 3rd argument is ...
917 #       movq    %r9,%rcx        ; if 4th argument ...
918 #       movq    40(%rsp),%r8    ; if 5th ...
919 #       movq    48(%rsp),%r9    ; if 6th ...
920 # endif
921 #       ...
922 # ifdef WIN64

928 ################################################
929 # Win64 SEH, Structured Exception Handling.
930 #
931 # Unlike on Unix systems(*) lack of Win64 stack unwinding information
932 # has undesired side-effect at run-time: if an exception is raised in
933 # assembler subroutine such as those in question (basically we're
934 # referring to segmentation violations caused by malformed input
935 # parameters), the application is briskly terminated without invoking
936 # any exception handlers, most notably without generating memory dump
937 # or any user notification whatsoever. This poses a problem. It's
938 # possible to address it by registering custom language-specific
939 # handler that would restore processor context to the state at
940 # subroutine entry point and return "exception is not handled, keep
941 # unwinding" code. Writing such handler can be a challenge... But it's
942 # doable, though requires certain coding convention. Consider following
943 # snippet:
944 #
945 # .type function,@function
946 # function:
947 #       movq    %rsp,%rax       # copy rsp to volatile register
948 #       pushq   %r15            # save non-volatile registers
949 #       pushq   %rbx
950 #       pushq   %rbp
951 #       movq    %rsp,%r11
952 #       subq    %rdi,%r11       # prepare [variable] stack frame
953 #       andq    $-64,%r11
954 #       movq    %rax,0(%r11)    # check for exceptions
955 #       movq    %r11,%rsp       # allocate [variable] stack frame
956 #       movq    %rax,0(%rsp)    # save original rsp value
957 # magic_point:
958 #       ...
959 #       movq    0(%rsp),%rcx    # pull original rsp value
960 #       movq    -24(%rcx),%rbp  # restore non-volatile registers
961 #       movq    -16(%rcx),%rbx
962 #       movq    -8(%rcx),%r15
963 #       movq    %rcx,%rsp       # restore original rsp
964 #       ret
965 # .size function,.-function
966 #
967 # The key is that up to magic_point copy of original rsp value remains
968 # in chosen volatile register and no non-volatile register, except for
969 # rsp, is modified. While past magic_point rsp remains constant till
970 # the very end of the function. In this case custom language-specific
971 # exception handler would look like this:
972 #
973 # EXCEPTION_DISPOSITION handler (EXCEPTION_RECORD *rec,ULONG64 frame,
974 #               CONTEXT *context,DISPATCHER_CONTEXT *disp)
975 # {     ULONG64 *rsp = (ULONG64 *)context->Rax;
976 #       if (context->Rip >= magic_point)
977 #       {   rsp = ((ULONG64 **)context->Rsp)[0];
978 #           context->Rbp = rsp[-3];
979 #           context->Rbx = rsp[-2];
980 #           context->R15 = rsp[-1];
981 #       }
982 #       context->Rsp = (ULONG64)rsp;
983 #       context->Rdi = rsp[1];
984 #       context->Rsi = rsp[2];
985 #
986 #       memcpy (disp->ContextRecord,context,sizeof(CONTEXT));
987 #       RtlVirtualUnwind(UNW_FLAG_NHANDLER,disp->ImageBase,
988 #               dips->ControlPc,disp->FunctionEntry,disp->ContextRecord,
989 #               &disp->HandlerData,&disp->EstablisherFrame,NULL);
990 #       return ExceptionContinueSearch;
991 # }
992 #
993 # It's appropriate to implement this handler in assembler, directly in
```

```
 994 # function's module. In order to do that one has to know members'
 995 # offsets in CONTEXT and DISPATCHER_CONTEXT structures and some constant
 996 # values. Here they are:
 997 #
 998 #       CONTEXT.Rax                             120
 999 #       CONTEXT.Rcx                             128
1000 #       CONTEXT.Rdx                             136
1001 #       CONTEXT.Rbx                             144
1002 #       CONTEXT.Rsp                             152
1003 #       CONTEXT.Rbp                             160
1004 #       CONTEXT.Rsi                             168
1005 #       CONTEXT.Rdi                             176
1006 #       CONTEXT.R8                              184
1007 #       CONTEXT.R9                              192
1008 #       CONTEXT.R10                             200
1009 #       CONTEXT.R11                             208
1010 #       CONTEXT.R12                             216
1011 #       CONTEXT.R13                             224
1012 #       CONTEXT.R14                             232
1013 #       CONTEXT.R15                             240
1014 #       CONTEXT.Rip                             248
1015 #       CONTEXT.Xmm6                            512
1016 #       sizeof(CONTEXT)                         1232
1017 #       DISPATCHER_CONTEXT.ControlPc            0
1018 #       DISPATCHER_CONTEXT.ImageBase            8
1019 #       DISPATCHER_CONTEXT.FunctionEntry        16
1020 #       DISPATCHER_CONTEXT.EstablisherFrame     24
1021 #       DISPATCHER_CONTEXT.TargetIp             32
1022 #       DISPATCHER_CONTEXT.ContextRecord        40
1023 #       DISPATCHER_CONTEXT.LanguageHandler      48
1024 #       DISPATCHER_CONTEXT.HandlerData          56
1025 #       UNW_FLAG_NHANDLER                       0
1026 #       ExceptionContinueSearch                 1
1027 #
1028 # In order to tie the handler to the function one has to compose
1029 # couple of structures: one for .xdata segment and one for .pdata.
1030 #
1031 # UNWIND_INFO structure for .xdata segment would be
1032 #
1033 # function_unwind_info:
1034 #       .byte   9,0,0,0
1035 #       .rva    handler
1036 #
1037 # This structure designates exception handler for a function with
1038 # zero-length prologue, no stack frame or frame register.
1039 #
1040 # To facilitate composing of .pdata structures, auto-generated "gear"
1041 # prologue copies rsp value to rax and denotes next instruction with
1042 # .LSEH_begin_{function_name} label. This essentially defines the SEH
1043 # styling rule mentioned in the beginning. Position of this label is
1044 # chosen in such manner that possible exceptions raised in the "gear"
1045 # prologue would be accounted to caller and unwound from latter's frame.
1046 # End of function is marked with respective .LSEH_end_{function_name}
1047 # label. To summarize, .pdata segment would contain
1048 #
1049 #       .rva    .LSEH_begin_function
1050 #       .rva    .LSEH_end_function
1051 #       .rva    function_unwind_info
1052 #
1053 # Reference to functon_unwind_info from .xdata segment is the anchor.
1054 # In case you wonder why references are 32-bit .rvas and not 64-bit
1055 # .quads. References put into these two segments are required to be
1056 # *relative* to the base address of the current binary module, a.k.a.
1057 # image base. No Win64 module, be it .exe or .dll, can be larger than
1058 # 2GB and thus such relative references can be and are accommodated in
1059 # 32 bits.
```

```
1060 #
1061 # Having reviewed the example function code, one can argue that "movq
1062 # %rsp,%rax" above is redundant. It is not! Keep in mind that on Unix
1063 # rax would contain an undefined value. If this "offends" you, use
1064 # another register and refrain from modifying rax till magic_point is
1065 # reached, i.e. as if it was a non-volatile register. If more registers
1066 # are required prior [variable] frame setup is completed, note that
1067 # nobody says that you can have only one "magic point." You can
1068 # "liberate" non-volatile registers by denoting last stack off-load
1069 # instruction and reflecting it in finer grade unwind logic in handler.
1070 # After all, isn't it why it's called *language-specific* handler...
1071 #
1072 # Attentive reader can notice that exceptions would be mishandled in
1073 # auto-generated "gear" epilogue. Well, exception effectively can't
1074 # occur there, because if memory area used by it was subject to
1075 # segmentation violation, then it would be raised upon call to the
1076 # function (and as already mentioned be accounted to caller, which is
1077 # not a problem). If you're still not comfortable, then define tail
1078 # "magic point" just prior ret instruction and have handler treat it...
1079 #
1080 # (*)   Note that we're talking about run-time, not debug-time. Lack of
1081 #       unwind information makes debugging hard on both Windows and
1082 #       Unix. "Unlike" referes to the fact that on Unix signal handler
1083 #       will always be invoked, core dumped and appropriate exit code
1084 #       returned to parent (for user notification).
1085 #endif /* ! codereview */

/*
```

```
 * Query the EGD <URL: http://www.lothar.com/tech/crypto/>.
 *
 * This module supplies three routines:
 *
 * RAND_query_egd_bytes(path, buf, bytes)
 *   will actually query "bytes" bytes of entropy form the egd-socket located
 *   at path and will write them to buf (if supplied) or will directly feed
 *   it to RAND_seed() if buf==NULL.
 *   The number of bytes is not limited by the maximum chunk size of EGD,
 *   which is 255 bytes. If more than 255 bytes are wanted, several chunks
 *   of entropy bytes are requested. The connection is left open until the
 *   query is competed.
 *   RAND_query_egd_bytes() returns with
 *     -1  if an error occured during connection or communication.
 *     num the number of bytes read from the EGD socket. This number is either
 *         the number of bytes requested or smaller, if the EGD pool is
 *         drained and the daemon signals that the pool is empty.
 *   This routine does not touch any RAND_status(). This is necessary, since
 *   PRNG functions may call it during initialization.
 *
 * RAND_egd_bytes(path, bytes) will query "bytes" bytes and have them
 *   used to seed the PRNG.
 *   RAND_egd_bytes() is a wrapper for RAND_query_egd_bytes() with buf=NULL.
 *   Unlike RAND_query_egd_bytes(), RAND_status() is used to test the
 *   seed status so that the return value can reflect the seed state:
 *     -1  if an error occured during connection or communication _or_
 *         if the PRNG has still not received the required seeding.
 *     num the number of bytes read from the EGD socket. This number is either
 *         the number of bytes requested or smaller, if the EGD pool is
 *         drained and the daemon signals that the pool is empty.
 *
 * RAND_egd(path) will query 255 bytes and use the bytes retreived to seed
 *   the PRNG.
 *   RAND_egd() is a wrapper for RAND_egd_bytes() with numbytes=255.

/* The following algorithm repeatedly samples the real-time clock
   (RTC) to generate a sequence of unpredictable data.  The algorithm
   relies upon the uneven execution speed of the code (due to factors
   such as cache misses, interrupts, bus activity, and scheduling) and
   upon the rather large relative difference between the speed of the
   clock and the rate at which it can be read.

   If this code is ported to an environment where execution speed is
   more constant or where the RTC ticks at a much slower rate, or the
   clock can be read with fewer instructions, it is likely that the
   results would be far more predictable.

   As a precaution, we generate 4 times the minimum required amount of
   seed data.  */

219 #ifdef OPENSSL_SYS_VMS
220         /* VMS NOTE: Prior versions of this routine created a _new_
221          * version of the rand file for each call into this routine, then
222          * deleted all existing versions named ;-1, and finally renamed
223          * the current version as ';1'. Under concurrent usage, this
224          * resulted in an RMS race condition in rename() which could
225          * orphan files (see vms message help for RMS$_REENT). With the
226          * fopen() calls below, openssl/VMS now shares the top-level
227          * version of the rand file. Note that there may still be
228          * conditions where the top-level rand file is locked. If so, this
229          * code will then create a new version of the rand file. Without
230          * the delete and rename code, this can result in ascending file
231          * versions that stop at version 32767, and this routine will then
232          * return an error. The remedy for this is to recode the calling
233          * application to avoid concurrent use of the rand file, or
234          * synchronize usage at the application level. Also consider
235          * whether or not you NEED a persistent rand file in a concurrent
236          * use situation.

/* EME-OAEP as defined in RFC 2437 (PKCS #1 v2.0) */

/* See Victor Shoup, "OAEP reconsidered," Nov. 2000,
 * <URL: http://www.shoup.net/papers/oaep.ps.Z>
 * for problems with the security proof for the
 * original OAEP scheme, which EME-OAEP is based on.
 *
 * A new proof can be found in E. Fujisaki, T. Okamoto,
 * D. Pointcheval, J. Stern, "RSA-OEAP is Still Alive!",
 * Dec. 2000, <URL: http://eprint.iacr.org/2000/061/>.
 * The new proof has stronger requirements for the
 * underlying permutation: "partial-one-wayness" instead
 * of one-wayness.  For the RSA function, this is
 * an equivalent notion.
