794 /* Handle include of header files.
795  * The relevant options are made compatible with gcc. The only options that
796  * are not supported is -withprefix and friends.
797  *
798  * Three set of include paths are known:
799  * quote_includepath:   Path to search when using #include "file.h"
800  * angle_includepath:   Paths to search when using #include <file.h>
801  * isys_includepath:    Paths specified with -isystem, come before the
802  *                      built-in system include paths. Gcc would suppress
803  *                      warnings from system headers. Here we separate
804  *                      them from the angle_ ones to keep search ordering.
805  *
806  * sys_includepath:     Built-in include paths.
807  * dirafter_includepath Paths added with -dirafter.
808  *
809  * The above is implemented as one array with pointers
810  *                          +--------------+
811  * quote_includepath --->   |              |
812  *                          +--------------+
813  *                          |              |
814  *                          +--------------+
815  * angle_includepath --->   |              |
816  *                          +--------------+
817  * isys_includepath  --->   |              |
818  *                          +--------------+
819  * sys_includepath   --->   |              |
820  *                          +--------------+
821  * dirafter_includepath ->  |              |
822  *                          +--------------+
823  *
824  * -I dir insert dir just before isys_includepath and move the rest
825  * -I- makes all dirs specified with -I before to quote dirs only and
826  *   angle_includepath is set equal to isys_includepath.
827  * -nostdinc removes all sys dirs by storing NULL in entry pointed
828  *   to by * sys_includepath. Note that this will reset all dirs built-in
829  *   and added before -nostdinc by -isystem and -idirafter.
830  * -isystem dir adds dir where isys_includepath points adding this dir as
831  *   first systemdir
832  * -idirafter dir adds dir to the end of the list
833  */

/*
 * The point here is to store the relationships between two variables.
 * Ie:  y > x.
 * To do that we create a state with the two variables in alphabetical order:
 * ->name = "x vs y" and the state would be "<".  On the false path the state
 * would be ">=".
 *
 * Part of the trick of it is that if x or y is modified then we need to reset
 * the state.  We need to keep a list of all the states which depend on x and
 * all the states which depend on y.  The link_id code handles this.

/*
 * The simplest type of condition is
 * if (a) { ...
 *
 * The next simplest kind of conditions is
 * if (a && b) { c;
 * In that case 'a' is true when we get to 'b' and both are true
 * when we get to c.
 *
 * Or's are a little more complicated.
 * if (a || b) { c;
 * We know 'a' is not true when we get to 'b' but it may be true
 * when we get to c.
 *
 * If we mix and's and or's that's even more complicated.
 * if (a && b && c || a && d) { d ;
 * 'a' is true when we evaluate 'b', and 'd'.
 * 'b' is true when we evaluate 'c' but otherwise we don't.
 *
 * The other thing that complicates matters is if we negate
 * some if conditions.
 * if (!a) { ...
 * Smatch has passes the un-negated version to the client and flip
 * the true and false values internally.  This makes it easier
 * to write checks.
 *
 * And negations can be part of a compound.
 * if (a && !(b || c)) { d;
 * In that situation we multiply the negative through to simplify
 * stuff so that we can remove the parens like this:
 * if (a && !b && !c) { d;
 *
 * One other thing is that:
 * if ((a) != 0){ ...
 * that's basically the same as testing for just 'a' and we simplify
 * comparisons with zero before passing it to the script.
 *

/*
 * Basically I see constraints as a way of saying "x <= some_limit".  The
 * problem is that smatch_capped is not granullar enough.
 *
 * This is mostly for finding out of bounds errors.  So there are different
 * types of constraints.  Quite often we have "foo->xxx[i] = 42;" and we want
 * to verify that "i" is less than foo->size.
 *
 * My idea was that we could automatically figure out these constraints.  And we
 * could load them in the DB so that they are the same every time.  As in a
 * constraint could be "< (struct whatever)->size" and give that in ID that
 * would be constant until you completely wiped the DB.  So when you do a normal
 * DB rebuild then the first thing it will do is preserve all the constraints.
 * I guess the reason to do it this way is to save space...  I sometimes suspect
 * that worrying about saving space is premature optimization.
 *
 * The other thing that I want to do a little bit different here is how I merge
 * constraints.  If a constraint is true on both sides, then that's normal.  If
 * we merge constraint 23 and 67 then we get constraint 23|67.  If we merge 23
 * with &undefined then we get &undefined.  We can also have two constraints
 * that are both true so we could have (45&23)|12 which means either both 45 and
 * 23 are true or 12 is true.
 *

/*
 * It's pretty common that the return value implies something about a parameter.
 * This gives you a way to tell Smatch about it.
 *
 * The format is:
 * function "return range" parameter "implied value range list of parameter"
 *
 * You have to specify at least two return ranges for a function.  The implied
 * value is a range list, but the return range is just a range and we only care
 * about the min and the max.  We start counting the first parameter at zero.
 *

978          * The ordering here is sort of important.
979          * One example, of how this matters is that when we do:
980          *
981          *      len = strlen(str);
982          *
983          * That is handled by smatch_common_functions.c and smatch_strlen.c.
984          * They use implied_return and function_assign_hook respectively.
```

```
985          * We want to get the implied return first before we do the function
986          * assignment hook otherwise we end up writing the wrong thing for len
987          * in smatch_extra.c because we assume that it already holds the
988          * strlen() when we haven't set it yet.

/*
 * Imagine we have this code:
 * foo = 1;
 * if (bar)
 *         foo = 99;
 * else
 *         frob();
 *                   //  <-- point #1
 * if (foo == 99)    //  <-- point #2
 *         bar->baz; //  <-- point #3
 *
 *
 * At point #3 bar is non null and can be dereferenced.
 *
 * It's smatch_implied.c which sets bar to non null at point #2.
 *
 * At point #1 merge_slist() stores the list of states from both
 * the true and false paths.  On the true path foo == 99 and on
 * the false path foo == 1.  merge_slist() sets their pool
 * list to show the other states which were there when foo == 99.
 *
 * When it comes to the if (foo == 99) the smatch implied hook
 * looks for all the pools where foo was not 99.  It makes a list
 * of those.
 *
 * Then for bar (and all the other states) it says, ok bar is a
 * merged state that came from these previous states.  We'll
 * chop out all the states where it came from a pool where
 * foo != 99 and merge it all back together.
 *
 * That is the implied state of bar.
 *
 * merge_slist() sets up ->pool.  An sm_state only has one ->pool and
 *    that is the pool where it was first set.  The my pool gets set when
 *    code paths merge.  States that have been set since the last merge do
 *    not have a ->pool.
 * merge_sm_state() sets ->left and ->right.  (These are the states which were
 *    merged to form the current state.)
 * a pool:  a pool is an slist that has been merged with another slist.

/*
 * One problem that I have is that it's really hard to track how pointers are
 * passed around.  For example, it would be nice to know that the probe() and
 * remove() functions get the same pci_dev pointer.  It would be good to know
 * what pointers we're passing to the open() and close() functions.  But that
 * information gets lost in a call tree full of function pointer calls.
 *
 * I think the first step is to start naming specific pointers.  So when a
 * pointer is allocated, then it gets a tag.  So calls to kmalloc() generate a
 * tag.  But we might not use that, because there might be a better name like
 * framebuffer_alloc(). The framebuffer_alloc() is interesting because there is
 * one per driver and it's passed around to all the file operations.
 *
 * Perhaps we could make a list of functions like framebuffer_alloc() which take
 * a size and say that those are the interesting alloc functions.
 *
 * Another place where we would maybe name the pointer is when they are passed
 * to the probe().  Because that's an important pointer, since there is one
 * per driver (sort of).
 *
 * My vision is that you could take a pointer and trace it back to a global.  So
 * I'm going to track that pointer_tag - 28 bytes takes you to another pointer
 * tag.  You could follow that one back and so on.  Also when we pass a pointer
 * to a function that would be recorded as sort of a link or path or something.
 *

/*
 * The point here is to store the relationships between two variables.
 * Ie:  y > x.
 * To do that we create a state with the two variables in alphabetical order:
 * ->name = "x vs y" and the state would be "<".  On the false path the state
 * would be ">=".
 *
 * Part of the trick of it is that if x or y is modified then we need to reset
 * the state.  We need to keep a list of all the states which depend on x and
 * all the states which depend on y.  The link_id code handles this.
 *

/*
 * This is almost the same as smatch_param_filter.c.  The difference is that
 * this only deals with values passed on the stack and param filter only deals
 * with values changed so that the caller sees the new value.  It other words
 * the key for these should always be "$" and the key for param_filter should
 * never be "$".  Also smatch_param_set() should never use "$" as the key.
 * Param set should work together with param_filter to determine the value that
 * the caller sees at the end.
 *
 * This is for functions like this:
 *
 * int foo(int a)
 * {
 *       if (a >= 0 && a < 10) {
 *               a = 42;
 *               return 1;
 *       }
 *       return 0;
 * }
 *
 * If we pass in 5, it returns 1.
 *
 * It's a bit complicated because we can't just consider the final value, we
 * have to always consider the passed in value.
 *

/*
 * Take a look at request_threaded_irq().  It takes thread_fn and dev_id.  Then
 * it does:
 *
 *      action = kzalloc(sizeof(struct irqaction), GFP_KERNEL);
 *      action->thread_fn = thread_fn;
 *      action->dev_id = dev_id;
 *
 * It doesn't ever pass action back to the higher levels, but instead registers
 * it with the lower levels.
 *
 * The kzalloc() allocation creates a new mtag.  We don't know at this point
 * what "thread_fn" and "dev_id" are because they come from many different
 * sources.
 *
 * So what we do is we pass the information back to the callers that thread_fn
 * and dev_id are stored as a specific mtag data.  Then when the callers *do*
 * know what values are passed they create an mtag_alias.  An mtag_alias is a
 * many to one relationship.  Then they store that in mtag_data using the
 * mtag_alias.
 *
