3404 /*
3405  * It would be great if we could use pkcs11_kernel directly since this library
3406  * offers hardware slots only. That's the easiest way to achieve the situation
3407  * where we use the hardware accelerators when present and OpenSSL native code
3408  * otherwise. That presumes the fact that OpenSSL native code is faster than the
3409  * code in the soft token. It's a logical assumption - Crypto Framework has some
3410  * inherent overhead so going there for the software implementation of a
3411  * mechanism should be logically slower in contrast to the OpenSSL native code,
3412  * presuming that both implementations are of similar speed. For example, the
3413  * soft token for AES is roughly three times slower than OpenSSL for 64 byte
3414  * blocks and still 20% slower for 8KB blocks. So, if we want to ship products
3415  * that use the PKCS#11 engine by default, we must somehow avoid that regression
3416  * on machines without hardware acceleration. That's why switching to the
3417  * pkcs11_kernel library seems like a very good idea.
3418  *
3419  * The problem is that OpenSSL built with SunStudio is roughly 2x slower for
3420  * asymmetric operations (RSA/DSA/DH) than the soft token built with the same
3421  * compiler. That means that if we switched to pkcs11_kernel from the libpkcs11
3422  * library, we would have had a performance regression on machines without
3423  * hardware acceleration for asymmetric operations for all applications that use
3424  * the PKCS#11 engine. There is one such application - Apache web server since
3425  * it's shipped configured to use the PKCS#11 engine by default. Having said
3426  * that, we can't switch to the pkcs11_kernel library now and have to come with
3427  * a solution that, on non-accelerated machines, uses the OpenSSL native code

```

```

3428 * for all symmetric ciphers and digests while it uses the soft token for
3429 * asymmetric operations.
3430 *
3431 * This is the idea: dlopen() pkcs11_kernel directly and find out what
3432 * mechanisms are there. We don't care about duplications (more slots can
3433 * support the same mechanism), we just want to know what mechanisms can be
3434 * possibly supported in hardware on that particular machine. As said before,
3435 * pkcs11_kernel will show you hardware providers only.
3436 *
3437 * Then, we rely on the fact that since we use libpkcs11 library we will find
3438 * the metaslot. When we go through the metaslot's mechanisms for symmetric
3439 * ciphers and digests, we check that any found mechanism is in the table
3440 * created using the pkcs11_kernel library. So, as a result we have two arrays
3441 * of mechanisms that were advertised as supported in hardware which was the
3442 * goal of that whole exercise. Thus, we can use libpkcs11 but avoid soft token
3443 * code for symmetric ciphers and digests. See pk11_choose_slots() for more
3444 * information.
3445 *
3446 * This is Solaris specific code, if SOLARIS_HW_SLOT_SELECTION is not defined
3447 * the code won't be used.

```
62 Why BIO_f_reliable?

64 I wrote function which took BIO* as argument, read data from it
65 and processed it. Then I wanted to store the input file in
66 encrypted form. OK I pushed BIO_f_cipher to the BIO stack
67 and everything was OK. BUT if user types wrong password
68 BIO_f_cipher outputs only garbage and my function crashes. Yes
69 I can and I should fix my function, but BIO_f_cipher is
70 easy way to add encryption support to many existing applications
71 and it's hard to debug and fix them all.

73 So I wanted another BIO which would catch the incorrect passwords and
74 file damages which cause garbage on BIO_f_cipher's output.

76 The easy way is to push the BIO_f_md and save the checksum at
77 the end of the file. However there are several problems with this
78 approach:

80 1) you must somehow separate checksum from actual data.
81 2) you need lot's of memory when reading the file, because you
82 must read to the end of the file and verify the checksum before
83 letting the application to read the data.
84
85 BIO_f_reliable tries to solve both problems, so that you can
86 read and write arbitrary long streams using only fixed amount
87 of memory.

89 BIO_f_reliable splits data stream into blocks. Each block is prefixed
90 with it's length and suffixed with it's digest. So you need only
91 several Kbytes of memory to buffer single block before verifying
92 it's digest.

94 BIO_f_reliable goes further and adds several important capabilities:

96 1) the digest of the block is computed over the whole stream
97 -- so nobody can rearrange the blocks or remove or replace them.

99 2) to detect invalid passwords right at the start BIO_f_reliable
100 adds special prefix to the stream. In order to avoid known plain-text
101 attacks this prefix is generated as follows:

103 *) digest is initialized with random seed instead of
104 standardized one.
105 *) same seed is written to output
106 *) well-known text is then hashed and the output
107 of the digest is also written to output.

109 reader can now read the seed from stream, hash the same string
110 and then compare the digest output.

112 Bad things: BIO_f_reliable knows what's going on in EVP_Digest. I
113 initially wrote and tested this code on x86 machine and wrote the
114 digests out in machine-dependent order :( There are people using
115 this code and I cannot change this easily without making existing
116 data files unreadable.

4  * Overhaul notes;
5  *
6  * This code is now *mostly* thread-safe. It is now easier to understand in what
7  * ways it is safe and in what ways it is not, which is an improvement. Firstly,
8  * all per-class stacks and index-counters for ex_data are stored in the same
9  * global LHASH table (keyed by class). This hash table uses locking for all
10 * access with the exception of CRYPTO_cleanup_all_ex_data(), which must only be
11 * called when no other threads can possibly race against it (even if it was
12 * locked, the race would mean it's possible the hash table might have been
13 * recreated after the cleanup). As classes can only be added to the hash table,
14 * and within each class, the stack of methods can only be incremented, the
15 * locking mechanics are simpler than they would otherwise be. For example, the
16 * new/dup/free ex_data functions will lock the hash table, copy the method
17 * pointers it needs from the relevant class, then unlock the hash table before
18 * actually applying those method pointers to the task of the new/dup/free
19 * operations. As they can't be removed from the method-stack, only
20 * supplemented, there's no race conditions associated with using them outside
21 * the lock. The get/set_ex_data functions are not locked because they do not
22 * involve this global state at all - they operate directly with a previously
23 * obtained per-class method index and a particular "ex_data" variable. These
24 * variables are usually instantiated per-context (eg. each RSA structure has
25 * one) so locking on read/write access to that variable can be locked locally
26 * if required (eg. using the "RSA" lock to synchronise access to a
27 * per-RSA-structure ex_data variable if required).
28 * [Geoff]

59 /* Code for dynamic hash table routines
60 * Author - Eric Young v 2.0
61 */
```

new/usr/src/lib/openssl/libsunw_crypto/lhash/lhash.c

2

```
62 * 2.2 eay - added #include "crypto.h" so the memory leak checking code is
63 * present. eay 18-Jun-98
64 *
65 * 2.1 eay - Added an 'error in last operation' flag. eay 6-May-98
66 *
67 * 2.0 eay - Fixed a bug that occurred when using lh_delete
68 * from inside lh_doall(). As entries were deleted,
69 * the 'table' was 'contract()'ed, making some entries
70 * jump from the end of the table to the start, there by
71 * skipping the lh_doall() processing. eay - 4/12/95
72 *
73 * 1.9 eay - Fixed a memory leak in lh_free, the LHASH_NODES
74 * were not being free()ed. 21/11/95
75 *
76 * 1.8 eay - Put the stats routines into a separate file, lh_stats.c
77 * 19/09/95
78 *
79 * 1.7 eay - Removed the fputs() for realloc failures - the code
80 * should silently tolerate them. I have also fixed things
81 * lint complained about 04/05/95
82 *
83 * 1.6 eay - Fixed an invalid pointers in contract/expand 27/07/92
84 *
85 * 1.5 eay - Fixed a misuse of realloc in expand 02/03/1992
86 *
87 * 1.4 eay - Fixed lh_doall so the function can call lh_delete 28/05/91
88 *
89 * 1.3 eay - Fixed a few lint problems 19/3/1991
90 *
91 * 1.2 eay - Fixed lh_doall problem 13/3/1991
92 *
93 * 1.1 eay - Added lh_doall
94 *
95 * 1.0 eay - First version

20  * Trouble with Ciphertext Stealing, CTS, mode is that there is no
21  * common official specification, but couple of cipher/application
22  * specific ones: RFC2040 and RFC3962. Then there is 'Proposal to
23  * Extend CBC Mode By "Ciphertext Stealing"' at NIST site, which
24  * deviates from mentioned RFCs. Most notably it allows input to be
25  * of block length and it doesn't flip the order of the last two
26  * blocks. CTS is being discussed even in ECB context, but it's not
27  * adopted for any known application. This implementation provides
28  * two interfaces: one compliant with above mentioned RFCs and one
29  * compliant with the NIST proposal, both extending CBC mode.

85 /*
86 * Even though permitted values for TABLE_BITS are 8, 4 and 1, it should
87 * never be set to 8. 8 is effectively reserved for testing purposes.
88 * TABLE_BITS>1 are lookup-table-driven implementations referred to as
89 * "Shoup's" in GCM specification. In other words OpenSSL does not cover
90 * whole spectrum of possible table driven implementations. Why? In
91 * non-"Shoup's" case memory access pattern is segmented in such manner,
92 * that it's trivial to see that cache timing information can reveal
93 * fair portion of intermediate hash value. Given that ciphertext is
94 * always available to attacker, it's possible for him to attempt to
95 * deduce secret parameter H and if successful, tamper with messages
96 * [which is nothing but trivial in CTR mode]. In "Shoup's" case it's
97 * not as trivial, but there is no reason to believe that it's resistant
98 * to cache-timing attack. And the thing about "8-bit" implementation is
99 * that it consumes 16 (sixteen) times more memory, 4KB per individual
100 * key + 1KB shared. Well, on pros side it should be twice as fast as
101 * "4-bit" version. And for gcc-generated x86[_64] code, "8-bit" version
102 * was observed to run ~75% faster, closer to 100% for commercial
103 * compilers... Yet "4-bit" procedure is preferred, because it's
104 * believed to provide better security-performance balance and adequate
105 * all-round performance. "All-round" refers to things like:
106 *
107 * - shorter setup time effectively improves overall timing for
108 *   handling short messages;
109 * - larger table allocation can become unbearable because of VM
110 *   subsystem penalties (for example on Windows large enough free
111 *   results in VM working set trimming, meaning that consequent
112 *   malloc would immediately incur working set expansion);
113 * - larger table has larger cache footprint, which can affect
114 *   performance of other code paths (not necessarily even from same
115 *   thread in Hyper-Threading world);
116 *
117 * Value of 1 is not appropriate for performance reasons.

1 #!/usr/bin/env perl
2 #
3 # =====
4 # Written by Andy Polyakov <appro@fy.chalmers.se> for the OpenSSL
5 # project. The module is, however, dual licensed under OpenSSL and
6 # CRYPTOGAMS licenses depending on where you obtain it. For further
7 # details see http://www.openssl.org/~appro/cryptogams/.
8 # =====
9 #
10 # Version 4.3.
11 #
12 # You might fail to appreciate this module performance from the first
13 # try. If compared to "vanilla" linux-ia32-icc target, i.e. considered
14 # to be *the* best Intel C compiler without -KPIC, performance appears
15 # to be virtually identical... But try to re-configure with shared
16 # library support... Aha! Intel compiler "suddenly" lags behind by 30%
17 # [on P4, more on others:-) And if compared to position-independent
18 # code generated by GNU C, this code performs *more* than *twice* as
19 # fast! Yes, all this buzz about PIC means that unlike other hand-
20 # coded implementations, this one was explicitly designed to be safe
21 # to use even in shared library context... This also means that this
22 # code isn't necessarily absolutely fastest "ever," because in order
23 # to achieve position independence an extra register has to be
24 # off-loaded to stack, which affects the benchmark result.
25 #
26 # Special note about instruction choice. Do you recall RC4_INT code
27 # performing poorly on P4? It might be the time to figure out why.
28 # RC4_INT code implies effective address calculations in base+offset*4
29 # form. Trouble is that it seems that offset scaling turned to be
30 # critical path... At least eliminating scaling resulted in 2.8x RC4
31 # performance improvement [as you might recall]. As AES code is hungry
32 # for scaling too, I [try to] avoid the latter by favoring off-by-2
33 # shifts and masking the result with 0xFF<<2 instead of "boring" 0xFF.
34 #
35 # As was shown by Dean Gaudet <dean@arctic.org>, the above note turned
36 # void. Performance improvement with off-by-2 shifts was observed on
37 # intermediate implementation, which was spilling yet another register
38 # to stack... Final offset*4 code below runs just a tad faster on P4,
39 # but exhibits up to 10% improvement on other cores.
40 #
41 # Second version is "monolithic" replacement for aes_core.c, which in
42 # addition to AES_[de]ncrypt implements private_AES_set_[de]ncryption_key.
43 # This made it possible to implement little-endian variant of the
44 # algorithm without modifying the base C code. Motivating factor for
45 # the undertaken effort was that it appeared that in tight IA-32
46 # register window little-endian flavor could achieve slightly higher
47 # Instruction Level Parallelism, and it indeed resulted in up to 15%
48 # better performance on most recent µ-archs...
49 #
50 # Third version adds AES_cbc_encrypt implementation, which resulted in
51 # up to 40% performance improvement of CBC benchmark results. 40% was
52 # observed on P4 core, where "overall" improvement coefficient, i.e. if
53 # compared to PIC generated by GCC and in CBC mode, was observed to be
54 # as large as 4x:-) CBC performance is virtually identical to ECB now
55 # and on some platforms even better, e.g. 17.6 "small" cycles/byte on
56 # Opteron, because certain function prologues and epilogues are
57 # effectively taken out of the loop...
58 #
59 # Version 3.2 implements compressed tables and prefetch of these tables
60 # in CBC[!] mode. Former means that 3/4 of table references are now
61 # misaligned, which unfortunately has negative impact on elder IA-32
```

new/usr/src/lib/openssl/libsunw_crypto/pl/aes-586.pl

2

```
62 # implementations, Pentium suffered 30% penalty, PIII - 10%.
63 #
64 # Version 3.3 avoids L1 cache aliasing between stack frame and
65 # S-boxes, and 3.4 - L1 cache aliasing even between key schedule. The
66 # latter is achieved by copying the key schedule to controlled place in
67 # stack. This unfortunately has rather strong impact on small block CBC
68 # performance, ~2x deterioration on 16-byte block if compared to 3.3.
69 #
70 # Version 3.5 checks if there is L1 cache aliasing between user-supplied
71 # key schedule and S-boxes and abstains from copying the former if
72 # there is no. This allows end-user to consciously retain small block
73 # performance by aligning key schedule in specific manner.
74 #
75 # Version 3.6 compresses Td4 to 256 bytes and prefetches it in ECB.
76 #
77 # Current ECB performance numbers for 128-bit key in CPU cycles per
78 # processed byte [measure commonly used by AES benchmarks] are:
79 #
80 #             small footprint      fully unrolled
81 # P4           24                  22
82 # AMD K8       20                  19
83 # PIII        25                  23
84 # Pentium     81                  78
85 #
86 # Version 3.7 reimplements outer rounds as "compact." Meaning that
87 # first and last rounds reference compact 256 bytes S-box. This means
88 # that first round consumes a lot more CPU cycles and that encrypt
89 # and decrypt performance becomes asymmetric. Encrypt performance
90 # drops by 10-12%, while decrypt - by 20-25%:-( 256 bytes S-box is
91 # aggressively pre-fetched.
92 #
93 # Version 4.0 effectively rolls back to 3.6 and instead implements
94 # additional set of functions, _[x86|sse]_AES_[en|de]crypt_compact,
95 # which use exclusively 256 byte S-box. These functions are to be
96 # called in modes not concealing plain text, such as ECB, or when
97 # we're asked to process smaller amount of data [or unconditionally
98 # on hyper-threading CPU]. Currently it's called unconditionally from
99 # AES_[en|de]crypt, which affects all modes, but CBC. CBC routine
100 # still needs to be modified to switch between slower and faster
101 # mode when appropriate... But in either case benchmark landscape
102 # changes dramatically and below numbers are CPU cycles per processed
103 # byte for 128-bit key.
104 #
105 #             ECB encrypt      ECB decrypt      CBC large chunk
106 # P4           56[60]          84[100]          23
107 # AMD K8       48[44]          70[79]           18
108 # PIII        41[50]          61[91]           24
109 # Core 2       32[38]          45[70]          18.5
110 # Pentium     120             160             77
111 #
112 # Version 4.1 switches to compact S-box even in key schedule setup.
113 #
114 # Version 4.2 prefetches compact S-box in every SSE round or in other
115 # words every cache-line is *guaranteed* to be accessed within ~50
116 # cycles window. Why just SSE? Because it's needed on hyper-threading
117 # CPU! Which is also why it's prefetched with 64 byte stride. Best
118 # part is that it has no negative effect on performance:-)
119 #
120 # Version 4.3 implements switch between compact and non-compact block
121 # functions in AES_cbc_encrypt depending on how much data was asked
122 # to be processed in one stroke.
123 #
124 # =====
125 # Timing attacks are classified in two classes: synchronous when
126 # attacker consciously initiates cryptographic operation and collects
127 # timing data of various character afterwards, and asynchronous when
```

```

128 # malicious code is executed on same CPU simultaneously with AES,
129 # instruments itself and performs statistical analysis of this data.
130 #
131 # As far as synchronous attacks go the root to the AES timing
132 # vulnerability is twofold. Firstly, of 256 S-box elements at most 160
133 # are referred to in single 128-bit block operation. Well, in C
134 # implementation with 4 distinct tables it's actually as little as 40
135 # references per 256 elements table, but anyway... Secondly, even
136 # though S-box elements are clustered into smaller amount of cache-
137 # lines, smaller than 160 and even 40, it turned out that for certain
138 # plain-text pattern[s] or simply put chosen plain-text and given key
139 # few cache-lines remain unaccessed during block operation. Now, if
140 # attacker can figure out this access pattern, he can deduct the key
141 # [or at least part of it]. The natural way to mitigate this kind of
142 # attacks is to minimize the amount of cache-lines in S-box and/or
143 # prefetch them to ensure that every one is accessed for more uniform
144 # timing. But note that *if* plain-text was concealed in such way that
145 # input to block function is distributed *uniformly*, then attack
146 # wouldn't apply. Now note that some encryption modes, most notably
147 # CBC, do mask the plain-text in this exact way [secure cipher output
148 # is distributed uniformly]. Yes, one still might find input that
149 # would reveal the information about given key, but if amount of
150 # candidate inputs to be tried is larger than amount of possible key
151 # combinations then attack becomes infeasible. This is why revised
152 # AES_cbc_encrypt "dares" to switch to larger S-box when larger chunk
153 # of data is to be processed in one stroke. The current size limit of
154 # 512 bytes is chosen to provide same [diminishingly low] probability
155 # for cache-line to remain untouched in large chunk operation with
156 # large S-box as for single block operation with compact S-box and
157 # surely needs more careful consideration...
158 #
159 # As for asynchronous attacks. There are two flavours: attacker code
160 # being interleaved with AES on hyper-threading CPU at *instruction*
161 # level, and two processes time sharing single core. As for latter.
162 # Two vectors. 1. Given that attacker process has higher priority,
163 # yield execution to process performing AES just before timer fires
164 # off the scheduler, immediately regain control of CPU and analyze the
165 # cache state. For this attack to be efficient attacker would have to
166 # effectively slow down the operation by several *orders* of magnitude,
167 # by ratio of time slice to duration of handful of AES rounds, which
168 # unlikely to remain unnoticed. Not to mention that this also means
169 # that he would spend correspondingly more time to collect enough
170 # statistical data to mount the attack. It's probably appropriate to
171 # say that if adversary reckons that this attack is beneficial and
172 # risks to be noticed, you probably have larger problems having him
173 # mere opportunity. In other words suggested code design expects you
174 # to preclude/mitigate this attack by overall system security design.
175 # 2. Attacker manages to make his code interrupt driven. In order for
176 # this kind of attack to be feasible, interrupt rate has to be high
177 # enough, again comparable to duration of handful of AES rounds. But
178 # is there interrupt source of such rate? Hardly, not even 16bps NIC
179 # generates interrupts at such raging rate...
180 #
181 # And now back to the former, hyper-threading CPU or more specifically
182 # Intel P4. Recall that asynchronous attack implies that malicious
183 # code instruments itself. And naturally instrumentation granularity
184 # has to be noticeably lower than duration of codepath accessing S-box.
185 # Given that all cache-lines are accessed during that time that is.
186 # Current implementation accesses *all* cache-lines within ~50 cycles
187 # window, which is actually *less* than RDTSC latency on Intel P4!

594 #####
595 # Why not xmm registers? Short answer. It was actually tested and
596 # was not any faster, but "contrary", most notably on Intel CPUs.
597 # Longer answer. Main advantage of using mm registers is that movd
598 # latency is lower, especially on Intel P4. While arithmetic
599 # instructions are twice as many, they can be scheduled every cycle
600 # and not every second one when they are operating on xmm register,
601 # so that "arithmetic throughput" remains virtually the same. And
602 # finally the code can be executed even on elder SSE-only CPUs:-)
